PRINCIPLES AND PRACTICE

OF

DENTAL SURGERY,

BY

CHAPIN A. HARRIS, M.D., D.D.S.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF DENTAL SURGERY IN THE BALTIMORE
COLLEGE; MEMBER OF THE AMERICAN MEDICAL ASSOCIATION; AUTHOR OF DIC-
TIONARY OF MEDICAL TERMINOLOGY, DENTAL SURGERY AND THE
COLLATERAL SCIENCES, ETC., ETC.

SEVENTH EDITION:

ENLARGED AND IMPROVED.

WITH

TWO HUNDRED AND SEVENTY ILLUSTRATIONS.

PHILADELPHIA:

LINDSAY & BLAKISTON.

1858.

ENTERED, according to the act of Congress, in the year one thousand eight hundred and fifty-eight, by LINDSAY & BLAKISTON, in the Clerk's Office of the District Court of the Eastern District of Pennsylvania.

JOHN W. WOODS, PRINTER,

BALTIMORE.

Biond

1858

TO

THOMAS E. BOND, M. D.

PROFESSOR OF SPECIAL PATHOLOGY AND THERAPEUTICS IN THE BALTIMORE COLLEGE OF
DENTAL SURGERY,

AS A TOKEN OF GRATITUDE FOR MUCH KINDNESS, AND AS A
TESTIMONY OF RESPECT AND ESTEEM FOR GREAT
PROFESSIONAL AND PRIVATE WORTH,

THIS VOLUME

IS RESPECTFULLY DEDICATED,

BY HIS FRIEND,

AND OBEDIENT SERVANT,

THE AUTHOR.

P R E F A C E

T O T H E S E V E N T H E D I T I O N .

IN revising his Principles and Practice of Dental Surgery for a Seventh Edition, the author trusts that no abatement of effort will be discovered on his part to render it every way worthy of a continuance of the approbation it has hitherto received. Nearly every page has been carefully revised, and additions have been introduced throughout the entire work. Three new chapters and a number of illustrative cuts have also been added. In short, he believes that no valuable improvement or discovery, coming within the scope of this work, has been omitted in the present edition.

CHAPIN A. HARRIS.

No. 51 NORTH CHARLES-ST. }
BALTIMORE, *Sept.* 1858. }

P R E F A C E

T O T H E F I F T H E D I T I O N .

THE Fourth Edition of this work having been disposed of, a Fifth is called for. In this, the author has endeavored, as he did in each of the preceding editions, to present a faithful exposé of the state of the Science and Art of Dental Surgery up to the time of its publication. The improvements introduced into it, will, he believes, be found fully if not more than equal to those of any of the preceding editions. The whole work has been revised, and numerous additions made to almost every chapter. In the part devoted to Mechanical Dentistry three new chapters have been added.

The author indulges the hope that his efforts to keep pace with the progress of the art will be found satisfactory to his readers, and that, independently of the advantages they may find from the added matter, they will be gratified to perceive, in the necessity for it, the evidence of a progress in Dentistry most cheering to all who desire to see this branch of Surgery rescued from the domain of ignorant empiricism.

The great improvement made within the few years past, gives good reason to expect that this department of Medicine will soon receive the public and professional consideration it deserves. To be instrumental in bringing about a result so desirable is the sincere and long cherished hope of the author.

P R E F A C E

T O T H E S E C O N D E D I T I O N .

IN submitting to the profession a Second Edition of his Dental Practice, the author is happy to avail himself of the opportunity to express his grateful appreciation of the approbation which the First has received. He trusts that the additions which he has made to the primary work will make the one now presented still more acceptable. The alteration in the plan, which has resulted from the effort at improvement, has, however, rendered a slight change of title necessary, in order to express the character of the present book.

In the First Edition, the Anatomy of the Mouth was omitted, because a thorough knowledge of it can be obtained from works on General Anatomy. But it has been suggested that such works may not be at

hand when wanted by the dental student, and the author has thought it better to furnish a description of the several structures which enter into the formation of this cavity. He has, however, confined himself to brief expositions of the parts; not wishing to encumber the work, or distract the student with the consideration of matters foreign to the purpose for which it was written, and for which he trusts, it will be read. He is indebted to Bourger's Anatomy, Quain and Wilson's Anatomical Plates, Wilson's Anatomy, and Smith and Horner's Anatomical Atlas, for a number of the illustrations used in this part of the work.

The second and fifth parts embody the substance of two papers, by the author, which were written subsequently to the publication of the first edition. The subjects of them came properly within the plan of the present work.

The object of the author in the preparation of this edition has been to provide a thorough elementary treatise on Dental Medicine and Surgery, which might be a text book for the student and a guide to the more inexperienced practitioner, and he hopes that the modifications he has introduced, and the additions he has made, will entitle it to be so considered, at least, until an abler hand shall prepare a better.

CONTENTS.

PART FIRST.

	PAGE.
ANATOMY AND PHYSIOLOGY OF THE MOUTH,	27
Elements of the Mouth,	27

CHAPTER FIRST.

ORGANS OF PREHENSION,	28
Origin and Insertion of these Muscles or their Attachments,	29
1. Levator Labii Superioris Alæque Nasi,	29
2. Levator Anguli Oris,	29
3. Depressor Labii Inferioris,	29
4. Depressor Anguli Oris,	30
5. Zygomaticus Major,	30
6. Zygomaticus Minor,	30
7. Buccinator,	30
8. Orbicularis Oris,	30
9. Depressor Labii Superioris,	30
10. Levator Labii Inferioris,	30

CHAPTER SECOND.

ORGANS OF MASTICATION,	31
Passive Organs of Mastication,	31
The Superior Maxillary Bones,	31
Inferior Maxillary Bone,	36
The Palate Bones,	39
The Teeth,	40
The Temporary Teeth,	41
The Permanent Teeth,	42
The Pulp,	43
The Dentine,	46
The Enamel,	54
The Cementum,	57

	PAGE.
Description of Teeth belonging to each Class,	59
The Incisors,	59
The Cuspidati,	61
The Bicuspids,	62
The Molars,	63
Articulation of the Teeth,	65
Difference between the Temporary and Permanent Teeth,	65
Relations of the Teeth of the Upper to those of the Lower Jaw, when the	
Mouth is closed,	66
Active Organs of Mastication,	67
The Temporal Muscles,	68
The Masseter Muscles,	68
Pterygoideus Externus,	69
Pterygoideus Internus,	70
CHAPTER THIRD.	
ORGANS OF INSALIVATION,	71
The Parotid Gland,	71
The Submaxillary,	72
The Sublingual Glands,	73
The Mucons Glands,	73
CHAPTER FOURTH.	
ORGANS OF DEGLUTITION,	75
The Pharynx,	75
The Soft Palate,	77
The Tongue,	80
The Mucons Membrane Lining the Mouth,	84
The Gums,	85
The Alveolo-Dental Periosteum,	86

OF
DENTAL SURGERY.

PART FIRST.

ANATOMY AND PHYSIOLOGY OF THE MOUTH.

THE MOUTH, containing the Dental Apparatus, is a very complicated piece of mechanism—forms an essential part of the human frame—has the widest possible range of sympathy—contains a great variety of organs—and performs an equally great variety of functions.

ELEMENTS OF THE MOUTH.

The anatomical elements composing the mouth, consist of Bone, Ligament, Muscle, Gland, Vessel, Nerve, Cellular and Adipose Tissue and Mucous Membrane.

These different elements combine together and form the various organs which constitute the mouth.

These organs I shall consider in their physiological order—thus combining their anatomy and physiology—or studying at the same time both their healthy structure and function—a plan practically taught by the late Professor W. R. Handy, in the Baltimore College of Dental Surgery, and which commends itself by being the most natural, interesting and instructive.

The mouth is bounded above by the palatine processes of the superior maxillary and palatine bones—below by the tongue and mylo-hyoid muscles—laterally by the cheeks—anteriorly by the lips—and posteriorly by the soft palate and fauces.

The mouth contains the organs of taste, and is concerned in the four primary stages of Digestion, namely :

Prehension, Mastication, Insalivation and Deglutition—besides being engaged in the intellectual acts of speech and expression.

CHAPTER FIRST.

ORGANS OF PREHENSION.

FIG. 1.

THIS class of organs may be said to commence digestion, and it comprises those which seize the food, and introduce and partly retain it in the mouth.

They consist of the Elevators, Depressors, and Sphinctor Muscles of the mouth, which are as follows :

1. Levator labii superioris alaeque nasi. *d*

2. Levator anguli oris. *o*

These two elevate the upper lip and angle of the mouth.

3. Depressor labii inferioris—or quadratus menti. *l*

FIG. 1. A front view of the muscles of the face: *a a* Anterior bellies of occipitofrontalis; *b b* Orbicularis palpebrarum; *c* Pyramidalis nasi; *d* Compressor nasi; *e e* and *f f* Levator labii superioris alaeque nasi; *g g* Zygomaticus minor; *h h* Zygomaticus major; *i i* Masseter muscle; *j j* Buccinator, or trumpeter's muscle; *k k* Orbicularis oris; *l l* Depressor labii inferioris; *m* Levator menti; *n n* Depressor anguli oris; *o o* Levator anguli oris.

4. Depressor anguli oris—or triangular oris.

These two antagonize the first and depress the lower lip and angles of the mouth.

5. Zygomaticus major.

6. Zygomaticus minor.

7. Buccinator.

These are situated to the outside of the angles of the mouth—in the direction from the angles to the prominence of the cheek.

Their use is to draw the angles of the mouth upwards and outwards towards the ear.

8. Obicularis oris.

This is the sphinctor muscle which surrounds and closes the mouth.

9. Depressor labii superioris.

10. Levator labii inferioris.

The one depresses the upper lip against the teeth—the other raises the lower lip.

ORIGIN AND INSERTION OF THESE MUSCLES OR THEIR ATTACHMENTS.

1. *Levator Labii Superioris Alaeque Nasi*, arises by two heads—first from the nasal process of the superior maxillary bone—second, from the edge of the orbit above the infra-orbital foramen. It is inserted into the ala nasi or wing of the nose and upper lip.

2. *Levator Anguli Oris*, arises from the canine fossa of the superior maxillary bone, immediately below the infra-orbital hole. It is inserted narrow into the angle of the mouth.

3. *Depressor Labii Inferioris*, arises from the side and front of the inferior maxilla at its base, and is inserted into the greater part of the lower lip.

4. *Depressor Anguli Oris*, arises broad and fleshy from the base of the lower jaw at the side of the chin. It is inserted into the angle of the mouth.

5. *Zygomaticus Major*, arises long and narrow from the malar bone, near the zygomatic suture. It is inserted into the angle of the mouth.

6. *Zygomaticus Minor*, arises from the front part of the malar bone, and is inserted into the upper lip, above the angle of the mouth.

This muscle is sometimes wanting—and is sometimes a simple slip from other muscles.

7. *Buccinator*, arises from the upper and lower jaws as far back as the coronoid and pterygoid processes, and from the alveolar ridge as far forwards as the bicuspid teeth. It is inserted into the angle of the mouth.

8. *Obicularis Oris*. This muscle has no bony attachments—it is circular, surrounds the mouth—and consists of two planes of fibres, one for the upper—the other for the lower lip, which meet at the angle of the mouth.

9. *Depressor Labii Superioris*, arises from the alveolar processes of the incisor and canine teeth; and is inserted into the upper lip and side of the ala nasi.

10. *Levator Labii Inferioris*, arises from the alveolar processes of the incisor teeth of the lower jaw. It is inserted into the lower lip and chin.

See Organs of Mastication for descriptions of bones concerned with these muscles.

CHAPTER SECOND.

ORGANS OF MASTICATION.

MASTICATION, as the term implies, is a process of chewing or reducing the food, when introduced into the mouth, into minute portions, and the organs under this head are the agents or instruments which effect this operation.

The organs of mastication are divided into, 1st. The passive. 2d. The active.

PASSIVE ORGANS OF MASTICATION.

The passive organs include the bones, ligaments and teeth.

The principal bones are,

1. The superior maxillary or upper jaw bone.
2. The inferior maxillary or lower jaw bone.
3. The palate bones.

THE SUPERIOR MAXILLARY BONES.

The *Superior Maxillary Bones*, being two in number, are in pairs and united on the median line of the face. They occupy the anterior upper part of the face, are of very irregular *form*, and consist of a body, processes and foramina.

The body is the central part of the bone and has four surfaces, namely, the anterior or facial surface, the posterior or pterygoid, the superior or orbital, and the inferior or palatine surface.

The *Anterior Surface* is irregularly convex, and has a depression about its centre just above the canine and first bicuspid teeth, called the canine fossa—immediately above which is the infra-orbital foramen for transmitting an artery and nerve of same name—its upper and inner edge forms part of the lower margin of the orbit—from the inner ex-

tremity of which proceeds upwards towards the nasal and frontal bones a long and rather flat process, the nasal process of the superior maxilla—it is of a pyramidal form ; its posterior edge forming the internal margin of the orbit and helping to make the lachrymal groove ; its anterior edge receives the cartilages of the nose ; its upper corresponds to

FIG. 2.

FIG. 3.

the nasal bones, and its summit to the frontal, while its outer surface gives attachment to muscles, and its inner enters into the formation of the nose.

FIG. 4.

From the lower edge of its *anterior surface*, the alveolar processes and cavities are formed—these consist in depressions of a more or less conical form and correspond to the number of teeth, or roots of teeth, they are intended to receive. See Fig. 4.

FIG. 2. *a* The body of the left superior maxillary ; *b* Canine fossa ; *c* Infra-orbital foramen ; *d* Incisive fossa ; *e* Harmonial suture of the two bones ; *f* Nasal spine ; *g* Semilunar notch of anterior nares ; *h* Nasal process ; *i* Articulation of lachrymal bone ; *j* Malar process ; *k* Tuberosity of superior maxillary ; *l* Cavity of the antrum ; *m* Lachrymal tubercle ; *n* Orbital process.

FIG. 3. *a* Nasal surface of left superior maxillary ; *b* Opening of antrum ; *c* In-

The bottom of each of these cavities is perforated by a small foramen, for the passage of nerves and blood vessels which go to the teeth. The alveolar border externally presents a fluted appearance—the projections and depressions correspond with the alveolar cavities and the septa which separate them from each other.

The *Posterior Surface* has a bulging, called tuberosity, which is connected to the palate bones, and bounds behind the antrum—is perforated by three or four small holes—the posterior dental canals which go to the alveoli of the molar teeth.

The *Lower Surface* extends from the alveolar processes in front to the horizontal plate of the palate bones behind, called the palatine processes, which are rough below, forming the roof of the mouth, and smooth above, making the floor of the nostrils. They are united along the median line, at the anterior part of which is the foramen incisivum, having two openings in the nares above, while there is but one in the mouth below.

The *Upper or Orbital Surface* is triangular in shape, with its base in front forming the anterior, lower and internal edge of the orbit—while its apex extends back to the bottom, it forms the floor of the orbit and roof of the antrum ; its internal edge is united to the lachrymal, ethmoid, and palate bones ; its external edge assists in forming the sphenomaxillary fissure, and along its central surface is seen a canal running from behind, forwards and inwards—the infra-orbital canal. This canal divides into two, the smaller is the *anterior dental*, which descends to the anterior alveoli along the front wall of the antrum—the other is the proper

ferior turbinated bone ; *d* Inferior meatus of nose into which the nasal duct opens ; *e* Nasal process ; *f* Semilunar notch of lachrymal bone ; *g* Nasal spine ; *h h* Palate process ; *i i* Alveolar process ; *j* Palate process of palate bone ; *k* Palate spine ; *l* Tuberosity of palate bone ; *m* Hamular process.

continuation of the canal and ends at the infra-orbital hole ; along the upper part of the line uniting the palatine processes there is a ridge, the *nasal crest*, for receiving the vomer, and at the anterior part of this crest there is a projection forwards, the *nasal spine* ; at the external and upper part of the body is a *malar process*, which articulates with the malar bone. This is opposite the summit of the maxillary sinus.

The body of the superior maxilla is occupied by a large and very important cavity called the *Antrum Highmoreanum*, or Maxillary Sinus. This cavity is somewhat triangular in shape, with its base generally looking to the nose, and its apex to the malar process. Its upper wall is formed by the floor of the orbit, its lower by the alveoli of the molar teeth, which sometimes perforate this cavity. The canine fossa bounds it in front, while the tuberosity closes it behind. But the shape of this cavity is exceedingly variable. In examining a collection of nearly one hundred in the Museum of the Baltimore Dental College, no two were found to be shaped alike, and this difference is as marked between the right and the left in the same, as in different subjects. The floor of some is nearly flat, but in the majority of cases it is very uneven, sometimes crossed by a single septum, varying from one-eighth to half an inch in height, at other times there are found three or four septa, dividing the lower part of the cavity into as many separate compartments, with the bottom or floor of no two on a level with each other. Some are perforated by the roots of one or more teeth ; at other times the roots of several teeth extend considerably above the level of the floor of the antrum covered by a lamina of bone not thicker than bank note paper. In other cases, the floor of the antrum is half an inch above the extremities of the roots of the teeth. This cavity also differs as much in size as it does in shape.

The opening of the antrum is, on its nasal portion or base, into the middle meatus of the nose, and in the skeleton is large, while in the natural state it is much contracted by

the ethmoid bone above, the inferior spongy bone below, the palate bone behind, and by the mucous membrane which passes through this opening and lines its interior.

This antrum communicates with the anterior ethmoidal cells and frontal sinus.

The structure of the upper jaw is thick and cellular in its alveolar and other processes.

It is articulated with two bones of the cranium, the frontal and ethmoid, and seven of the face, namely: the nasal, malar, lachrymal, palate, inferior spongy, vomer, to its fellow and also to the teeth.

Its development is very complicated, and is stated to be by as many osseous points as that of the body and its various processes. Ossification commences at a very early period of intra-uterine existence.* It may be seen as early as the thirtieth or thirty-fifth day after conception; and although at birth it has acquired but little height, it has increased considerably in breadth. But, at this period, the alveolar border, which constitutes the largest portion of the bone, is almost in contact with the orbit. The antrum, at this time, is scarcely perceptible, but as the vertical dimensions of the bone are increased, it gradually develops itself. With the loss of the teeth, the alveolar border nearly disappears, so that the vault of the palate loses its arched form, and becomes almost flat.

The *Lower Jaw*, Fig. 5, is the largest bone of the face, and though but one bone in the adult, it consists of two symmetrical pieces in the fetus.

It occupies the lower part of the face—has a semicircular form, and extends back to the base of the skull.

It is divided into the body and extremities.

The body is the middle and horizontal portion; this is divided along its centre by a ridge called the *symphysis*, which is the place of separation in the infant state; the middle portion projects at its inferior part into an eminence

* Some anatomists say, that it is at first divided into three parts.

called the *mental process* or chin; on each side of which is a depression for the muscles of the lower lip, and externally

INFERIOR MAXILLARY BONE.

FIG. 5.

FIG. 6.

to these depressions are two foramini, called *anterior mental*, for transmitting an artery and nerve of the same name.

The horizontal portion or sides extends backwards and outwards; and on the outer surface has an oblique line for the attachment of muscles.

On the inner surface of the middle part behind the chin, along the line of the symphysis, there is a chain of eminences called *genial processes*; to the superior of which the frenum linguae is attached, to the middle the genio-hyoglossi, and to the inferior the genio-hyoid muscles; on each side of these eminences are depressions for the sublingual glands; and on each side of these depressions there runs an oblique ridge upwards and outwards, to the anterior part of which is attached the mylo-hyoid muscle, and to the posterior part, the superior constrictor of the pharynx; this latter muscle is consequently involved more or less in the extraction of the last molar tooth. Below this line there is a groove for the mylo-hyoid nerve.

The upper edge of the body is surmounted by the *alveolar processes* and cavities, corresponding in number and size to the roots of the teeth. (See Fig. 6.) The alveolar border, in the fetus, constitutes nearly the whole of the body of the bone. After the loss of the teeth, this part of the inferior maxillary is gradually wasted. The alveolar border, in the lower jaw, describes a rather smaller arch than it does in the upper, and in both it is thinner anteriorly than posteriorly.

The lower edge, called the base, is rounded, obtuse, and receives the superficial fascia and platysma muscle.

The extremities of the body have two large processes rising up at an obtuse angle, named the *rami* of the lower jaw. These processes are flat and broad on their surfaces; the outer is covered by the masseter muscle; the inner has a

FIG. 5. The inferior maxillary: *a* Body of the bone; *b* Mental foramen; *c* The symphysis; *d d* Alveolar processes; *e* Ramus of the lower jaw; *f* Its angles; *g g* Coronoid processes; *h h* Sigmoid notch; *i i* Condylod processes; *j j* Neck of the condyles; *k* Inferior dental foramen; *l* Mylo-hyoidean ridge.

deep groove which leads to a large hole, the *posterior dental* or maxillary foramen, for transmitting the inferior dental nerves and vessels to the dental canal running along the roots of the teeth. This foramen is protected by a spine to which the internal lateral ligament is attached.

The ramus has a projection at its lower part which is the angle of the lower jaw; its upper ridge is curved, having a process at each end—the anterior one is the *coronoid process*; this is triangular, and has the temporal muscle inserted into it; the posterior is the *condyloid*, and articulates with the temporal bone. This process has a neck for the insertion of the external pterygoid muscle.

The structure of the inferior maxilla is compact externally, cellular within and traversed in the greater part of its extent by the inferior dental canal.

The lower jaw is developed by two centres of ossification, which meet at the symphysis. It articulates at each side by one of its condyles with the glenoid cavity of the temporal bone, situated at the base of the zygomatic process. This cavity is divided into two portions—an anterior and posterior. The former constitutes the articular portion, the latter lodges a process of the parotid gland. The two are separated by the fissure of Glasserius, *fissuri glasseri*, which transmits the chorda tympani nerve, the laxitor tympani muscle and the internal auditory vessel. It also gives attachment to the long process, *processus gracilis*, of the malleus.

Between this cavity and the condyle, there is interposed an interarticular cartilage, so moulded as to fit the two articular surfaces. The circumference of this being free, except where it adheres to the external lateral ligament and affords attachment to a few fibres of the external pterygoid muscle, facilitates the movements of the joint.

The union of this articulation is maintained by the external and internal lateral, and the stylo-maxillary ligaments. The external lateral is seen in Fig. 32.

THE PALATE BONES.

The palate bones, two in number, and in pairs, are situated at the back part of the superior maxillary bone, between its tuberosities and the pterygoid processes of the sphenoid bone. They are shaped precisely alike.

The palate bone is divided into three plates—the horizontal or palate, the vertical or nasal, and the orbital.

The palate plate is broad and on the same line with the palate processes of the superior maxillary bone; its upper surface is smooth, and forms the posterior floor of the nostrils—the lower surface is rough, and forms the posterior part of the roof of the mouth; its anterior edge is connected to the palate process of the upper jaw, and its posterior is thin and crescentic, to which is attached the *velum-pendulum palati* or soft palate; at the posterior point of the suture, uniting the two palate bones, there projects backwards a process called the *posterior nasal spine*, which gives origin to the *azygos-uvulae* muscle. The *vertical plate* ascends, helps to form the *nasal*, diminishes the opening into the antrum by projecting forward, and by its external posterior part, in conjunction with the pterygoid processes of the sphenoid bone, forms the *posterior palatine canal*; the lower orifice of which is seen on the margin of the palate plate, and called the *posterior palatine foramen*, which transmits the palatine nerve and artery to the soft palate; behind this foramen is often seen a smaller one passing through the base of the pterygoid process of this bone, and sending a filament of the same nerve to the palate.

The upper end of the vertical or nasal plate has two processes—the one is seen at the back of the orbit, called the *orbital* process; the other is posterior and fits to the under surface of the body of the sphenoid bone. Between these two processes there is a foramen, the *spheno-palatine*, which transmits to the nose a nerve and artery of the same name.

The palate bone articulates with six others, namely : the superior maxillary, inferior turbinated, vomer, sphenoid and ethmoid.

FIG. 7.

FIG. 8

The structure of this bone is very thin, and consists almost entirely of compact tissue. Its development, it is said, takes place by a single point of ossification at the place of the union of the vertical, horizontal and pyramidal portions.

These bones are all more or less related with the bones of the head—of which eight compose the cranium and fourteen the face. Those of the cranium are one frontal, two parietal, two temporal, one occipital, one sphenoid and one ethmoid. Those of the face are six pairs and two single bones ; the pairs are the two malars, two superior maxillary, two lachrymal, two nasal, two palatine and two inferior spongy. The vomer and inferior maxillary are the two single bones.

THE TEETH.

The teeth are the prime organs of mastication—are the hardest portions of the body, and occupy the alveolar cavi-

ties of both the upper and lower jaw. Although analogous in structure to bone, they are regarded, from their development, as a modification of mucous membrane.

A tooth is composed of four distinct substances: 1. The *pulp*, occupying the chamber in the crown and canal extending through the root; 2. The *dentine*, which constitutes the principal part of the organ; 3. The *enamel*, which forms the covering and protection of the crown; 4. The *cementum* or *crusta petrosa*, which covers the root. (See Fig. 9.)

The teeth of first dentition, termed the milk, temporary or deciduous teeth, and designed to supply merely the wants of childhood, are replaced with a larger, stronger and more numerous set. These are termed the permanent or adult teeth, and are intended to continue through life.

The anatomical divisions of a tooth are: 1. The crown or exposed part situated above the gum; 2. The root occupying the alveolar cavity or socket; 3. The neck which is the constricted portion between the crown and root.

THE TEMPORARY TEETH.

The temporary are divided into three classes: first, the incisors; second, the cuspidati; third, the molars, which are succeeded by the bicuspidati.

Fig. 9. *a* The coronal surface divested of enamel; *b* The dentine; *c* The cavity of the pulp; *d* The cementum, or crusta petrosa; *e* The enamel.

FIG. 10.

FIG. 11.

FIG. 12.

FIG. 13.

The temporary teeth are twenty in number, ten in each jaw, namely: four incisors, two cuspidati, and four molars.

The pulp cavity of a temporary tooth is larger in proportion to the size of the organ than in a permanent tooth.

THE PERMANENT TEETH.

There are thirty-two teeth in the permanent set, sixteen to each jaw—being an increase of twelve, over the temporary, designated as follows: incisors, four; cuspids, two; bicuspids, four; molars, six to each jaw. The third or last

FIG. 10. Front view of the temporary teeth.

molar is sometimes designated by the name of *dens sapientiæ* or wisdom tooth.

THE PULP.

The pulp, enclosed in the centre of the tooth, is the first developed part of the organ, and the part from which the dentine is formed. It is an exquisitely sensitive, highly vascular and nervous substance, of a reddish-gray color, enveloped in an exceedingly delicate, and apparently, structureless membrane, continuous with the alveolo-dental periosteum and adherent to the walls of the pulp cavity. This is designated by Mr. Thomas Bell "the proper membrane of the pulp," and by Purkinjé and Raschkow, "the performative membrane," because, in the formation of the dentine, the deposition of earthy salts commences in it.

FIG. 14.

FIG. 15.

The pulp, according to the two last mentioned authors, is composed of minute globules. Schwann describes it as consisting of globular nucleated cells, with vessels and nerves passing between them—the cells having the same radial course as the fibres of the dentine. According to the microscopic observations

FIG. 16.

FIG. 14. A portion of the body of the pulp, showing the cellular arrangement.

FIG. 15. A portion of a superficial layer of the pulp, showing the appearance of vesicles.

FIG. 16. A portion of the body of the pulp, showing another variety in the arrangement of the cells.

of Mr. Nasmyth, it is principally composed of minute vesicular cells, varying in size from the ten-thousandth to an

FIG. 17.

eighth of an inch in diameter, disposed in concentric layers, which, when mascerated, have an irregular reticular appear-

FIG. 17. *a* The vessels of the pulp of an upper central incisor injected, as seen under the microscope by means of a high magnifying power; *b* The natural size of the pulp.

ance, and are found to be interspersed with granules, the parenchyma being traversed by vessels having a vertical direction. See Figs. 14, 15 and 16, copied from Mr. Nasmyth's *Researches on the Development and Structure of the Teeth*.

Mr. Tomes describes it as consisting, from its earliest appearance, of a series of nucleated cells, united and supported by plasma, and, prior to the commencement of the formation of the dentine, of delicate areolar tissue, occupied by a thick, clear, homogeneous fluid or plasma. The pulp is liberally supplied with blood vessels, furnished by the trunk which enters its base. The ramifications of these vessels are distributed throughout its entire substance, forming a capillary net work which terminates in loops upon its surface.

The distribution of the vessels of the pulp are represented in Fig. 17, copied from the late work of Mr. Nasmyth, and made from an injected preparation of an upper central incisor. The communication of the arteries with the veins by means of a series of looped capillaries, presenting a densely matted appearance upon the surface, are here beautifully represented. The nerves of the pulp have a very similar arrangement in their distribution as the vessels, having, as may be seen in Fig. 18, like looped terminations.

Kölliker describes the pulp as consisting of an indistinctly fibrous connective tissue, containing many dispersed, rounded and elongated nuclei, with, occasionally, narrow bundles, somewhat like imperfect

FIG. 18.

FIG. 18. The nerves of the pulp of an upper adult bicuspid, magnified twenty diameters.

fetal connective tissue, filled with a fluid substance. Immediately beneath the structureless membrane in which these structures are inclosed, there is a layer, composed of many series of cells, cylindrical or pointed at one end, with long narrow nucleated nuclei, arranged perpendicularly to the surface of the pulp, like a cylinder of epithelium. This layer is described as being, from two to four one-hundredths of a line in thickness. These regular series, proceeding internally, become less and less distinct, "but the cells, without losing their radial arrangement, are more intermixed, and pass, finally, by shorter and rounder cells, without any sharp lines of demarkation, into the vascular tissue of the pulp." His description of the distribution of the vessels and nerves of the pulp is similar to that given by Mr. Nasmyth and Mr. Tomes.

The pulp, previous to the formation of the dentine, is inclosed in a sac, consisting of two laminae, an outer and inner. The former, is described by Mr. Hunter as being soft and spongy, and without vessels; and the latter to be extremely vascular and firm. Mr. Thomas Bell, on the other hand, contends that the outer is full of vessels, while the inner is destitute and more tender, and this opinion is supported by the microscopic researches of Mr. Nasmyth, who describes the internal lamina of the capsule, previous to its closing and forming a sac, as possessing no vessels, though the injections of Mr. Fox, would seem to prove the contrary. But as the author will again have occasion, when he comes to treat of the origin and formation of the teeth, to recur to this subject, he will not enlarge upon it in this place.

THE DENTINE.

The *dentine* (*b* Fig. 9) is a very hard, dense substance, constituting the inner and large portion of the crown and nearly the whole of the root of the tooth. It consists of earthy salts and animal matter. The former may be removed by the application of acid, leaving the latter entirely

separate, and by applying heat, the animal portion may be destroyed, leaving the earthy.

FIG. 19.

Dentine is harder than bone or cementum, but less dense than enamel. It is disposed in concentric layers, arranged, one within the other, parallel to the surface of the tooth—the last internal layer forming the boundary of the pulp-cavity. But in addition to this peculiar structural arrangement, it is, according to the microscopie observations of Purkinjé, Retzius and Müller, composed of minute tubes or hollow fibres, radiating from the pulp cavity to the periphery of the tooth, giving off, in their course, numerous branches, as seen in Fig. 19, sometimes terminating in small cells or corpuseles, and an amorphous or structureless intertubular substance. The doctrine of the tubularity of dentine is also sustained by the subsequent researches of Professor Owen, Mr. Tomes, Kölliker and several other microscopists ; while on the other

Dentine and cement from the root of a human incisor tooth, copied from Kölliker : *a* Dentinal fibres or tubes ; *b* Interglobular spaces, having the appearance of the *lacunæ* in bone ; *c* Smaller interglobular spaces ; *d* Commencement of the cement, with numerous canals close together ; *e* Its *lamellæ* ; *f* *Lacunæ* ; *g* Canals.

FIG. 20. Transverse section through the dental tubuli of the root of a human tooth, magnified 350 diameters, showing their numerous anastomoses.

hand, Mr. Alexander Nasmyth, equally distinguished as an odontologist, has seemingly demonstrated by a series of beautiful and highly interesting experiments, that the canaliculi or tubes of these gentlemen, are solid fibres "composed of a series of little masses, succeeding each other in a linear direction, like so many beads collected on a string." See Fig. 21.

FIG. 21.

The tubes radiate from the pulp cavity to the outer surface of the dentine, each tube making three principal or primary curves in its course, and presenting, when examined with a high magnifying power, numerous secondary undulations, which are less perceptible at the external extremity of the tubes than the middle, and still less in the temporary than in the permanent teeth. The diameter of the tubes, from their commencement to the middle of the outer third of their courses is estimated at $\frac{1}{4} \frac{1}{7}$ of a French line, but from this point their terminal branches rapidly diminish until they become invisible, or are lost in small irregular rounded cells. When examined under a magnifying power of from three to five hundred diameters, they are seen to branch by a dichotomous division and in their whole course to give off numerous lateral branches. The tubes are not mere excavations, but have special parietes, the undulations in them are ascribed to certain periodic movements in the pulp during the formation of the successive layers of dentine, and both Retzius and Müller represent them as containing granular masses of inorganic matter.*

FIG. 21. The nuclei of fibres of dentine, arranged in a linear series, as shown by Mr. Nasmyth.

* Müller's Physiology.

These tubes are represented as piercing every part of the surface of the pulp cavity, and according to Professor Owen, are about the $\frac{1}{1000}$ part of an inch in diameter; they radiate as before stated, from the inner to the peripheral surface of the dentine. "In the lower incisor and canine teeth," says the last mentioned author, "those from the middle of the summit of the pulp cavity, ascend vertically to the enamel covered surface of the dentine at the summit of the crown; the tubes on each side of these gradually incline outwards; those which go to the angles of the crown, forming an angle of 45° with the middle vertical tubes; at the sides of the crown the tubes incline still more outwards, until in the middle of the fang they become horizontal, and still lower, bend downwards."* The vertical tubes are described as being nearly straight, but as they begin to incline downwards, they present two, and usually three curves; at the sides of the crown and the upper half of the root they have a short concave bend towards the crown, then a longer curve in the opposite, and finally a third curve in the first direction, but having a general concave bend downwards. The course of the tubuli, however, may be seen in Fig. 9.

The secondary curvatures of the dentinal fibres, or tubes, are very numerous; the last mentioned author says, "two hundred may be counted in an extent of $\frac{1}{10}$ of an inch; the curvatures observed in these, both primary and secondary, are parallel. Professor Retzius describes certain striæ, running parallel with the pulp cavity, "like the annual rings in the trunk of a tree." These circular lines are rarely seen in dentine of human teeth, though very observable in

FIG. 22.

FIG. 22. A section of dentine made transversely across the tubuli showing the opening into the tubes and their parietes, copied from Müller's Physiology.

* Owen's Odontology.

some animals, especially the elephant, and they are somewhat similar to the contour lines of Professor Owen, proceeding from "a short bend," occasionally observed in the tubes, "along a line parallel with the crown."

The dentinal fibres of the crown, in the teeth of the human subject, give off but few branches, until they arrive nearly to the outer surface of the dentine; the ramifications become more and more numerous towards the extremity of the root, and here, too, the terminal branches anastomose, more frequently with each other. In the crown they sometimes pass a short distance into the enamel, or terminate in small cavities near the surface, and it is here, or immediately upon the peripheral surface that dentine is most sensitive.

The researches of Mr. Nasmyth into the structure of dentine, as already intimated, do not accord with those of most other microscopists; he found, when sections made parallel to the fibres were submitted to the action of acid until the earthy salts were all taken up that the animal residue consisted of solid fibres, presenting an irregular or baccated appearance, being composed of numerous separate compartments or cells, corresponding exactly with the reticulations observed on the surface of the pulp, previous to the deposition of earthy salts, see Fig. 21. The shape and size of these cells, he describes as varying in different animals; in the human tooth as being oval, and as having their long axis corresponding with the course of the fibre, and the extremity of each in apposition to the one adjoining. The result of Mr. Nasmyth's investigations, it must be confessed, appears to justify the conclusion at which he has arrived in relation to this matter, but whether correct or erroneous, the author will not at present attempt to decide.

The interfibrous tissue constitutes a larger portion of the dentine in the root than in the crown of the tooth, and is supposed, by Purkinjé, Retzius, Müller, Kölliker, and other equally distinguished microscopists, to be structureless. Professor Owen and Mr. Nasmyth, describe it as cellular

Mr. Tomes says, "it is made up of minute granules, closely united." Professor Kölliker, calls it the matrix of the canals, or tubules, and affirms that it is "homogeneous," "without cells, fibres or other elements." The cells of Mr. Nasmyth and Professor Owen, are supposed by some to be nothing more than *intergranular*, or as they are designated by Czermák, interglobular spaces, and to consist of very minute irregular cavities: these spaces are observed more frequently in the crown near the enamel, where they seem to be composed of numerous thin layers, into which the contour lines, or as Salter calls them, contour-markings, enter. They are also described as being seen more internally near the pulp cavity and as being frequently pierced by the tubuli. The smaller spaces, from their communication with the tubules, have been regarded by some as identical with the *lacunæ* of bone. But Professor Kölliker states that he has rarely "observed actual *lacunæ* in normal dentine," and when present they were always at the boundary of the cement, but "interglobular spaces and dentinal globules" are met with in the interior of the root and on the walls of the pulp cavity, in which latter place they give rise to irregularities which may be seen with the naked eye. Again, he observes, "the interglobular spaces whose presence is normal in developing teeth, contain, during life, not fluid, as might at first be expected, but a soft substance resembling tooth cartilage and possessing a canaliculated structure, like the dentine itself. It is remarkable that this substance offers a greater resistance to long mastication in hydrochloric acid than the matrix of the actually ossified tooth, and, therefore, like the dentinal canals, it may be completely isolated. In sections, this *interglobular* substance usually dries up in such a manner that a cavity is produced, into which air penetrates." It is these, according to this author, which constitute the interglobular spaces, but there are many teeth in which this interglobular substance cannot be detected, where delicate arched outlines of dentinal globules may be observed. Each of these granules, if, indeed, the interfi-

brous tissue is made up in them, is enclosed in a delicate investment of animal matter, upon which exceedingly minute vessels are, no doubt, distributed.

Mr. Tomes describes a granular layer upon the surface of the root where the canals have become very small, in which, from the absence of the uniting medium of the granules, (the interglobular substance described by Professor Kölliker,) these spaces occur. He also states, that many of the terminal tubes communicates with these granular cells, as do others, which come from the cells of the cementum. The cells according to this author, frequently communicate with each other, though there does not appear to be any special provision for such communication.

Dentine is regarded by most microscopists, especially of human teeth, as destitute of vascular canals, but the author has seen ten or twelve specimens in which their existence was so clearly demonstrated as to leave no room for doubt. A description and drawing of one of which he published in the second volume of the *American Journal of Dental Science*. A similar one was shown to him by Dr. Maynard, of Washington City, and he has a section of a molar tooth made by Dr. Blandy, in which several vessels charged with red blood are distinctly seen. Mr. Tomes says he has seen eight or ten sections of vascular dentine, and he has given a drawing of one in which the dentine and cementum are both pierced by vascular canals.

Now, if vessels have been detected in dentine in so many instances, it seems more than probable that they are always present, though too small and attenuate to convey any thing but the thinnest and most serous part of the blood.

The delicate sensibility of dentine, especially when in a pathological condition, seems also to favor the opinion that nerve filaments are sent from the pulp to every part of this tissue, traversing, no doubt, the tubuli, which extend from the central chamber to the periphery. Believing dentine to be supplied with such filaments, Dr. Maynard stated to the author, several years ago, that, in removing diseased dentine

preparatory to filling, especially from the side of a tooth he found that his patient experienced much less pain when he applied the excavator to the part nearest the root and cut towards the coronal extremity, than when removed in the opposite direction. The microscopical researches of Professor Johnston of the Baltimore Dental College, seems also to demonstrate the fact that nerve filaments constitute an essential element of dentine.*

The surface of the dentine of the crown of a tooth, is, as stated by Professor Owen, marked by numerous pits, corresponding with the internal extremities of the enamel fibres, and into which they are received.

Every 100 parts of dentine, according to Berzelius, contains,

Phosphate of lime,	.	.	.	62.
Fluate of lime,	.	.	.	2.
Carbonate of lime,	.	.	.	5.5
Phosphate of magnesia,	.	.	.	1.

Inorganic substance,	79.00	71.99	71.30

*Am. Jour. Dent. Sci., July No., 1857, pp. 348.

The relative proportions, however, of the organic and inorganic matter are not always the same. They vary according to the density of the tooth.

The laminated decomposition which occurs in caries of the teeth is owing to the concentric arrangement of the dentine, or, according to Mr. Nasmyth, of the cells.

THE ENAMEL.

The *Enamel* (c Fig. 9) covers the crown, and extends to the neck of the tooth, but terminating sooner upon the approximal, than upon either of the other surfaces. It is the hardest of all animal substances, is pearly white, or slightly tinged with yellow, according to the texture of the tooth. Like the dentine, it varies in density, being harder on some teeth than others. It is thickest in those parts of the teeth most exposed to friction, as on the eminences of the molars and bicusps, and the cutting edges of the incisors and points of the cuspids, gradually diminishing to the line of its termination. The structure of the enamel, according to Mr. Nasmyth, is *fibro cellular*—the fibres radiating from the dentine to the surface of the tooth—an arrangement which gives to this outer investment immense strength and the power of sustaining great pressure. It has a smooth glossy surface, and on the permanent teeth, is characterized by delicate circular ridges and furrows, which, as stated by Czermák, are never seen on the temporary teeth. It is covered by a delicate ossified membrane, called by Professor Kölliker, the *cuticle of the enamel*, and by Huxley, *Nasmyth's membrane*, because Mr. Nasmyth was the discoverer of it. He terms it the "*persistent dental capsule*," and says it is continuous with the structure covering the root. It is similar to the membrane between the internal surface of the enamel and dentine, which constitutes the bond of union between the two. This membrane, according to Professor Kölliker, forms, from the great resistance it offers to chemical reagents, a peculiarly appropriate defence for the crown of the tooth.

FIG. 23.

FIG. 25.

FIG. 24.

The enamel is composed of prisms or fibres, for the most part of an hexagonal or pentagonal shape, arranged side by side with one extremity resting upon the dentine, or rather, upon the *intermediary* membrane, and the other upon *Nasmyth's membrane*, which, properly, constitutes the peripheral surface of the crown of the tooth. The fibres are marked, as seen in fig. 24 by transverse striæ, showing them to be, as is remarked by Professor Owen, "essentially the contents of extremely delicate membranous tubes, originally subdivided into minute depressed compartments or cells," and which, the author is inclined to believe constitutes the animal frame-work of the tissue, and probably, the bond of union between the fibres. The existence, however, of such uniting medium is not generally recognized by physiologists.

The prisms of the enamel have a wavy course, like the dentinal fibres of the crown of the tooth, the curvatures, for the most part, being parallel to each other, and more mark-

FIG. 23. The hexagonal terminations of the fibres of a portion of the surface of the enamel, highly magnified. At 1, 2, 3, the crooked crevices, between the hexagonal fibres, are more strongly marked.

FIG. 24. A side view of the enamel fibres magnified 350 diameters; 1 1, The enamel fibres; 2 2, transverse striæ upon them.

FIG. 25. The enamel seen on the face of a vertical section showing its cellular structure.

ed near the external than the internal surface. The curves, however, in the enamel fibres are shorter and more strongly marked than in the dental fibres. The prisms usually extend through the entire thickness of the enamel, but sometimes they fall short, and at other times they diverge near the external surface. When either of these happens, "shorter complimentary fibres fill up the interspace."

But in addition to the peculiar structural arrangement just described, the enamel, according to Mr. Nasmyth, is cellular. Each cell, as may be seen in Fig. 25, is of a semi-circular form, the convexity of the semicircle looking upwards towards the free external portion of the tooth.

Thus, by this most beautiful and peculiar structural arrangement, a capability of resisting mechanical force is given to the enamel, which its simple fibrous structure would wholly fail to supply.

The enamel, like the dentine, consists of organic and inorganic matter—the former being less than the latter. Its chemical composition, according to Berzelius, is,

Phosphate of lime,	85.3
Fluate of lime,	3.2
Carbonate of lime,	8.
Phosphate of magnesia,	1.5
Soda and muriate of soda,	1.
Animal matter and water,	1.

100.

Von Bibra makes it to consist of

	From a molar of a woman 25 years of age.	From a molar of an adult man.
Phosphate of lime, with some fluoride of calcium,	81.63	89.82
Carbonate of lime,	8.88	4.37
Phosphate of magnesia,	2.55	1.34
Salts,	0.97	0.88
Cartilage,	5.97	3.39
Fat,	a trace.	0.20
	<hr/> 100.00	<hr/> 100.00

Organic matters,	5.97	3.59
Inorganic matters,	94.03	96.51

These proportions, as in the case of dentine, are not always the same. They vary in the enamel of the teeth of different individuals.

THE CEMENTUM.

The *Cementum*, or *Crusta Petrosa*, (*d* Fig. 9,) covers the root, commencing where the enamel terminates, gradually increases in thickness to its apex. It has also been traced over the enamel, and Mr. Nasmyth, is of the opinion that it always invests the crowns of the teeth, but the author has never been able to detect it except upon the roots. If, therefore, it is formed upon the crown it is evidently soon worn off by the friction of mastication. The case mentioned by Purkinjé and Frankel, in which they discovered it upon the enamel of the teeth of an old man, is an exception to the general rule.

In many animals, however, it covers the crowns of the teeth, and sometimes unites vertical plates of enamel, into a solid tooth, as in the case of the molar teeth of the elephant.

Cementum corresponds in structure with the osseous tissue, being furnished with lacunæ, and, when of sufficient thickness, is traversed by vessels capable of conveying red blood. Mr. Tomes says, he has several specimens of healthy human teeth, in the cementum of which vascular canals exist, and in one, where two canals enter from the surface, anastomose, and give off three branches.

The cement, like dentine is arranged in concentric layers. It is also cellular—the cells, according to Mr. Tomes, being scattered through it “with some degree of regularity, generally, though not always, following a course as though placed between concentric laminae.” From the cells, tubes are given off which anastomose with each other and with those from contiguous cells. “By this arrangement,” says

the author last named, "a net-work of cells and tubes, permeable by fluids, is carried through the whole mass." He also states that "the majority of the radiating tubes pass, either towards the surface of the tooth, or, when such exists, towards the surface of a canal for a blood vessel. Many branches also go towards the dentine, and anastomose with the terminal branches of the dentinal tubes, while a few follow the course of the length of the tooth, anastomosing freely with tubes pursuing a like direction. Frequently, however, a cell with its tubuli resembles a tuft of moss, the tubes taking in a mass one direction only, and that towards a surface upon which blood vessels pass." The cells of the cement are usually oblong, as may be seen in Fig. 19, though sometimes they are circular and occasionally fusiform. They are as variable in size as in shape. The average of their long diameter is stated by Professor Owen to be about $\frac{1}{16}$ th of an inch.

The cement is much thicker on the permanent teeth than on the temporary, and it is thicker on the teeth of old persons than on those of young. In the former case it is often reflected into the pulp cavity at the extremity of the root, sometimes completely obliterating it at this point.

Cementum is composed, according to Von Bibra,

	In man.	In the ox.
Organic matters, . . .	29.42	32.24
Inorganic matters, . . .	70.58	67.76
	<hr/> 100.00	<hr/> 100.00

In the latter he found :

Phosphate of lime and fluoride of calcium,	58.73
Carbonate of lime,	7.22
Phosphate of magnesia,	0.99
Salts,	0.82
Cartilage,	31.31
Fat,	0.93
	<hr/> 100.00

Thus it is seen, that the cementum contains a larger proportion of organic matters than dentine, and hence, it is endowed with greater sensibility. This circumstance will account for the fact that, when the neck of a tooth becomes exposed by the recession of the gums, the slightest touch is often productive of severe pain. Still it is necessary to the preservation of the connection between the teeth and the general system, for if the dentine of the roots were not covered by it, these organs would act as irritants, and nature would at once make an effort to expel them from the body. In this, therefore, as in every thing else connected with the animal economy, wisdom of design is displayed.

DESCRIPTION OF TEETH BELONGING TO EACH CLASS.

Each tooth, as has already been remarked, has a body or crown, neck and root. In describing these several parts, I shall begin with

THE INCISORS.

The *Incisors* (four to each jaw, Fig. 26, *a a, a a,*) occupy the anterior central part of each maxillary arch. The body

FIG. 26.

FIG. 26. *a a, a a* Front view of the incisors; *b b, b b* Palatine and lingual view; *c c, c c* Side or lateral view.

of each is wedge shape—the anterior or labial surface is convex and smooth—the posterior or palatine is concave, and presents a tubercle near the neck; the palatine and labial surface come together, and form a cutting edge. In a front view, the edge is, generally, the widest part; it diminishes towards the neck, and continues narrowing to the extremity of the root.

The crown of an incisor has four surfaces, two *approximal*, one *labial*, and one *palatine* or *lingual surface*, the former being applied to an upper and the latter to a lower incisor. It also has four angles, namely, a *right* and a *left labio-approximal*, and a *right* and a *left palato-approximal* or *lingua-approximal*.

The two large incisors which are situated one on each side of the median line, are termed the central; the other two, the lateral incisors, or laterals. The crowns of the upper central incisors are about four lines in breadth, and the laterals three. In the lower jaw, the crowns of the central incisors are only about two lines and a half in width, while the laterals are usually a little wider. But the width of the crowns of all the incisors varies in different individuals.

The length of a superior central incisor is usually about one inch, and that of a lateral eleven lines and a half. In the lower jaw the central incisors are only about ten lines in length; the laterals are about one line and a half longer.

The length of the crown of an incisor is exceedingly variable. That of an upper central varies from four and a half to six lines, and there is the same want of uniformity in this respect with all the rest.

The roots are all single, of a conical form, flattened laterally, and slightly furrowed longitudinally. The enamel is thicker before than behind, and behind than at the sides.

The function of this class of teeth, as their names import, is to cut the food, and for the performance of this office they are admirably fitted by their shape. As age advances, their edges often become blunted, but the rapidity with which

they are worn away, depends altogether upon the manner in which those of the upper and lower jaw come together.

THE CUSPIDATI.

The *Cuspidati*, or *Canini*, (Fig. 27,) are situated next to the incisors, and are two to each jaw—one on either side. They somewhat resemble the upper central incisors with their angles rounded. Their crowns are conical, very convex externally, and their palatine surface more uneven, and having a larger tubercle than the incisors. Their roots are also larger, and the longest of all the teeth, and like the incisors, are also single, but have a groove extending from the neck to the extremity, showing a step at forming two roots. A cuspidatus, like an incisor, has four surfaces, and four angles, designated by the names already given.

The breadth of the crown of an upper cuspidatus is about four lines—that of a lower is about three and a half; but as in the case of the incisors, the width of the crowns of these teeth is variable. The length of a cuspidatus is greater than that of any other tooth in the dental series—it being about thirteen lines. The breadth of the neck of one of these teeth is about one-third greater in front than behind, and from before backwards it measures about four lines.

The upper cuspidati are called eye-teeth; the lower are termed stomach teeth.

These teeth are for tearing the food, and in some of the carnivorous animals where they are very large, they not only rend but also hold their prey.

The incisors and cuspidati together are termed the *oral* teeth.

Fig. 27.

FIG. 27. *a a* Front view of the cuspidati; *b b* Palatine and lingual view; *c c* Side view.

THE BICUSPIDS.

FIG. 28.

The *Bicuspids*, (Fig. 28,) four to each jaw, and two on either side, are next in order to the cuspidati. They are so called from their having two distinct prominences or cusps, on their friction surfaces. They are also named the small molars. They are thicker from their buccal to their palatine surface than either of the inci-

sors, and are flatter on their sides. The grinding surface of each is surmounted by two conicle tubercles, separated by a groove running in the direction of the alveolar arch; the outer is larger and more prominent than the inner. In the lower jaw these tubercles are smaller than in the upper, and on the first, the inner is sometimes wholly wanting.

A bicuspid has five surfaces, namely, two *approximal*, one *anterior* and one *posterior*, one *buccal*, one *palatine* or *lingual* surface, as the tooth may be in the upper or lower jaw, and one *grinding* surface. It has also four angles, one *anterior* and one *posterior palato-approximal*, and one *anterior* and one *posterior bucco-approximal* angle.

The size of these teeth, like that of the incisors and cuspidati, is variable. The buccal surface of the crown of a superior bicuspid of ordinary size at its broadest part, is about three lines in breadth, while the anterior and posterior approximal surfaces are about four lines. The palatine is not quite as wide as the buccal surface. All the diameters of the crown of a lower bicuspid are usually a

FIG. 28. *a a a* Buccal view of the bicuspid; *b b, b b* Palatine and lingual view; *c c, c c* Side view.

little less than those of an upper. The entire length of a bicuspid is ordinarily about eleven lines.

The roots of the bicuspids are, generally, simple, though the groove is deeper than in the cuspidati, and not unfrequently terminates in two roots, which have each an opening for the vessels and nerves to enter. The inner root, however, is always smaller than the outer.

THE MOLARS.

The *Molars* (Fig. 29) occupy the posterior part of the

FIG. 29.

FIG. 29. *a a a, a a a* Outer view of the molars; *b b b, b b b* Inner view; *c c c, c c c* Side view.

alveolar arch, and are six to each jaw, three on either side. They are distinguished by their greater size, the first and second being the largest; the grinding surfaces have the enamel thicker, and surmounted by four or five tubercles, or cusps, with as many corresponding depressions, arranged in such a manner that the tubercles of the upper jaw are

adapted to the depressions of the lower, and vice versa. A molar, like a bicuspid, has also five surfaces and five angles, designated by the names already given.

The upper molars have three roots, sometimes four, and as many as five are occasionally seen; of these roots two are situated exteriorly, almost parallel with each other, and perpendicular; the third root forms an acute angle, and looks to the roof of the mouth. The former are called the *buccal* roots, and the latter the *palatine*.

The lower molars have but two roots, the one anterior, the other posterior, are nearly vertical and parallel with each other and much flattened laterally. The roots of the two first superior molars correspond with the floor of the maxillary sinus, and sometimes protrude into this cavity, and their divergence secures them more firmly in their sockets.

The last molar, called the *dens sapientie*, or wisdom tooth, is both shorter and smaller than the others, the roots of the upper wisdom tooth are, occasionally, united so as to form but one—while the last molar of the lower jaw is generally single and of a conical form.

The roots of the molar teeth, both of the upper and lower jaw, after diverging, sometimes approach each other, embracing the intervening bony partition in such a manner as to constitute an obstacle to their extraction.

The bucco-palatine diameter of the crown of an upper molar is usually a little less than the antero-posterior. In the lower jaw, the bucco-lingual and antero-posterior diameters are generally about the same.

The crown of the first molar is generally larger than the second, and the second larger than the third or wisdom tooth, and the crown of the last named tooth is always smaller in the upper than in the lower jaw.

The length of a molar tooth varies from eight to twelve and a half to thirteen lines.

The molars and bicuspid together constitute what is termed the buccal teeth.

The use of the molars, as their term signifies, is to triturate or grind the food during mastication, and for which purpose they are admirably adapted by their mechanical arrangement.

ARTICULATION OF THE TEETH.

The manner in which the teeth are confined in their sockets, is by a union called *gomphosis*, from the resemblance of this kind of articulation to the way in which a nail is received into a board. Those teeth having but one root, and those with two perpendicular roots depend greatly on their nice adaptation to their sockets for the strength of their articulation.

Those having three or four roots rely mostly on their divergence for their firmness.

But there is another bond of union by the periosteum lining the alveolar cavities, and investing the roots of the teeth, also by the blood vessels entering the apices of the roots; and, finally, by the gums, which will be noticed in another place.

DIFFERENCE BETWEEN THE TEMPORARY AND PERMANENT TEETH.

The temporary and permanent teeth differ in several respects, and on this point I will give Mr. Bell's observations:

"The temporary teeth are, generally speaking, much smaller, than the permanent; of a less firm and solid texture, and their characteristic forms and prominences much less strongly marked. The incisors and cuspidati of the

lower jaw are of the same general form as the adult, though much smaller, the edges are more rounded, and they are not much more than half the length of the latter. The molars of the child, on the contrary, are considerably larger than the bicuspidis which succeed them, and resemble very nearly the permanent molars.

“The roots of these teeth, the molars of the child, are similar in number to those of the adult molars, but they are flatter and thinner in proportion, more hollowed on their inner surfaces, and diverge from the neck at a more abrupt angle, forming a sort of arch.”

RELATIONS OF THE TEETH OF THE UPPER TO THOSE OF THE LOWER JAW, WHEN THE MOUTH IS CLOSED.

The crowns of the teeth of the upper jaw, generally describe a rather larger arch than those of the lower. The upper incisors and cuspidati, usually shut over and in front of the lower, but sometimes they fall plumb upon them, and at other times, though rarely, they come on the inside. The external tubercles or cusps of the superior bicuspidis and molars, generally strike on the outside of those of the corresponding inferior teeth. By this beautiful adaptation of the tubercles of the teeth of one jaw to the depressions of those of the other, every part of the grinding surfaces of the organs are brought in immediate contact in the act of mastication, which operation of the teeth, in consequence, is rendered more perfect than it would be if the organs came together in any other manner. -

The incisors and cuspidati of the upper jaw are broader than the corresponding teeth in the lower; in consequence of this difference in the lateral diameter of the teeth of the two jaws, the central incisors of the upper cover the centrals and about half of the laterals in the lower, while the superior laterals cover the remaining half of the inferior and the anterior half of the adjoining cuspidati. Continuing this peculiar relationship, the upper cuspidati close over the re-

remaining half of the lower and the anterior half of the first inferior bicuspid, while the first superior bicuspid covers the remaining half of the first inferior and the anterior half of the second. In like manner, the second bicuspid of the upper jaw, close over the posterior half of the second in the lower, and the anterior third of the first molars. The first superior molars cover the remaining two-thirds of the first inferior and the anterior third of the second, while the uncovered two-thirds of this last and anterior third of the lower *dentes sapientiæ*, are covered by the second upper molars. The *dentes sapientiæ* of the superior maxillary being usually about one-third less in their antero-posterior diameter, cover the remaining two-thirds of the corresponding teeth in the inferior. (See Fig. 30.)

Thus, from this arrangement of the teeth, it will be seen, that when the mouth is closed, that each tooth is opposed to two, and, hence, in biting hard substances, and, in mastication, by extending this mutual aid, a power of resistance is given to these organs which they would not otherwise possess. Moreover, as a late English writer, Mr. Tomes, very justly observes, if one, or even two, adjoining teeth should be lost, the corresponding teeth in the other jaw would, to some extent, still act against the contiguous organs, and thus, in some degree, counteract a process, first noticed by that eminent dentist, Dr. L. Koecker, which nature sometimes sets up for the expulsion of such teeth as have lost their antagonists.

The order and time in which both temporary and permanent teeth appear, will be noticed in the chapters on First and Second Dentition.

ACTIVE ORGANS OF MASTICATION.

The active organs of mastication consist of the muscles attached, principally, to the upper and lower maxillary bones; by these, the various motions concerned in mastication are effected.

They are the temporalis, the masseter, pterygoideus externus, and the pterygoideus internus.

The *Temporal Muscle* (Fig. 31) is seen on the side of the head, and has its origin from the semicircular ridge commencing at the external angular process of the os-frontis, and extending along this and the parietal bones—also from the surfaces below this ridge formed by the frontal and squamous portion of the temporal and sphenoid bones; likewise from the under surface of the temporal aponeurosis, a strong fascia covering this muscle, and is inserted, after having its fibres to converge and passing under the zygoma, in the coronoid process of the lower jaw, surrounding it on every side by a dense strong tendon.

FIG. 31.

The office of this muscle is to bring the two jaws together, as in the cutting and rending of the food.

The *Masseter Muscle* (Fig. 32) is seen at the side and back part of the face in front of the meatus externus, and superficially under the skin. It arises by two portions, the

FIG. 31. *a* Side view of the temporal muscle, exposed by the removal of the temporal fascia; *b* External lateral ligament of the lower jaw; *c* Insertion of temporal muscle in coronoid process of lower jaw.

FIG. 32.

one anterior and tendinous from the superior maxilla where it joins the malar bone, the other portions, mostly fleshy, from the inferior edge of the malar bone and the zygomatic arch as far back as the glenoid cavity, and is inserted, tendinous and fleshy, into the external side of the ramus of the jaw and its angle as far up as the coronoid process.

The use of this muscle, when both portions act together, is to close the jaws; if the anterior acts alone, the jaw is brought forward, if the posterior, it is drawn backward.

Pterygoideus Externus (*a* and *b* Fig. 33) arises from the outer surface of the external plate of the pterygoid process of the sphenoid bone, from the tuberosity of the superior maxilla; also, from the ridge on the sphenoid bone separating the zygomatic from the pterygoid fossa, and is inserted into the inner side of the neck of the lower jaw, and capsular ligament of the articulation.

FIG. 32. Side view of the muscles of external ear, cranium and face: *a* Occipito-frontalis; *b* Orbicularis palpebrarum; *c* Pyramidalis nasi; *d* Compressor nasi; *e* and *f* Levator labii superioris alaeque nasi; *g* Zygomaticus minor; *h* Zygomaticus major; *i* Masseter Muscle; *j* Buccinator muscle; *k* Depressor anguli oris; *l* Depressor labii inferioris; *m* Orbicularis oris; *n* Anterior oris; *o* Superior oris; *p* Posterior oris; *q* External lateral ligament; *r* Deep-seated portion of masseter muscle; *s* Temporal fascia.

Pterygoideus Internus arises, tendinous and fleshy, from the inner surface of the pterygoid plate—fills up the greater part of the pterygoid fossa, and is inserted, tendinous and fleshy, in the inner face of the angle of the inferior maxilla and rough surface above the angle.

These two muscles are the great agents in producing the grinding motion of the jaws, and this they do by acting alternately.

The external one is triangular, having its base at the pterygoid process and running outwards and backwards to the neck of the condyle. When the pair act together, the lower jaw is thrown forwards. The internal is strong and thick, placed on the inside of the ramus of the jaw, and running downwards and backwards to the angle. When it and its fellow act together, the jaw is drawn forwards and closed.

FIG. 33.

FIG. 33. *a* and *b* Superior and inferior portions of the pterygoideus externus; *c* Pterygoideus internus; *d* Root of zygomatic process; *e* Condyle.

CHAPTER THIRD.

ORGANS OF INSALIVATION.

THE organs of insalivation are the salivary glands, six in number—three on each side of the face, named the *Parotid*, *Submaxillary* and *Sublingual*.

These glands are the prime organs in furnishing the salivary fluids to the mouth during the process of mastication.

FIG. 34.

The *Parotid Gland*, (a Fig. 34,) so called from its situation near the ear, is the largest of the salivary glands. Its form is very irregular; it fills all that space between the ramus of the inferior maxilla and mastoid process of the

FIG. 34. View of the salivary glands: a Parotid gland; b Submaxillary gland; c Sublingual glands; d Duct of Steno; e Duct of Wharton, or submaxillary duct.

temporal bone, and as deep back and even behind the styloid process of the same bone. Its extent of surface is from the zygoma above to the angle of the lower jaw below, and from the mastoid process and meatus externus behind to the masseter muscle in front, overlapping its posterior portion.

This gland is one of the conglomerate order, and consists of numerous small granular bodies connected together by cellular tissue, and each of which may be considered a small gland in miniature, as each is supplied with an artery, vein and secretory duct.

The gland thus formed, presents on its external surface a pale, flat, and somewhat convex appearance.

It is covered by a dense strong fascia extending from the neck, attached to the meatus externus of the ear, and sends countless processes into every part of the gland separating its lobules, and conducting the vessels through its substance.

The use of this gland is to secrete or separate from the blood the greater part of the saliva furnished the mouth. As the parotid is, however, on the outside, and at some little distance from the mouth, it is furnished with a duct to convey its fluid into this cavity; this duct is called the duct of *Steno*, or the parotid duct.

It is formed of the excretory ducts of all the granules composing this gland, which, successively uniting together at last form one common duct.

The duct of *Steno* commences at the anterior part of the gland and passes over the masseter muscle, on a line drawn from the lobe of the ear to the middle part of the upper lip, then passes through a quantity of soft adipose matter, and, finally, enters the mouth by passing through the buccinator muscle and mucous membrane opposite the second molaris of the upper jaw.

The *Submaxillary* (b Fig. 34) is the next in size of the salivary glands. It is situated under and along the inferior edge of the body of the lower jaw, and separated from the parotid simply by a process of fascia between the two.

It is of oval form, pale color, and like the parotid, consists in its structure of small granulations held together by cellular tissue, and each having a small excretory duct, which, successfully uniting with one another, finally form one common duct—the duct of Wharton, which passes above the mylo-hyoid muscle, and running forwards and inwards enters the mouth below the tip of the tongue at a papilla seen on either side of the frænum linguæ.

The use of this gland is the same as the parotid, to secrete the saliva, and its duct is the route by which it is conducted into the mouth.

The *Sublingual Glands* (c Fig. 34) are the last of the salivary order, and the smallest in size.

They are situated beneath the anterior and lateral parts of the tongue, and covered by the mucous membrane, and resting on the mylo-hyoid muscle.

They, like the two glands just described, consist of a granular structure with excretory ducts, which, however, do not unite into one common duct, but enter the cavity of the mouth by many ducts, whose openings are through the mucous membrane between the tongue and inferior cuspid and bicuspid teeth.

Their office is the same as the parotid and submaxillary.

FIG. 35.

The *Mucous Glands*, (Fig. 35.) Besides the glands furnishing the saliva, there is another series of much smaller size, called the mucous glands. They are simply the little

FIG. 35. A view of inner side of the lips, with the mucous membrane removed so as to show the labial and buccal glands: *a a* Ducts of Steno; *b b* Labial glands.

crypts, follicles, or depressions every where found in the mucous membrane of the mouth, and named, according to their situation, the *glandulæ labiales*, *glandulæ buccales*, etc. The lips, cheeks and palate are also furnished with glands, which present the true salivary structure.

The use of these glands is to furnish the mucous of the mouth, which they pour into this cavity, by single orifices, opening every where on its surface.

CHAPTER FOURTH.

ORGANS OF DEGLUTITION.

The *Organs of Deglutition* succeed next in the physiological order, and are the last in the series belonging to the mouth as concerned in the primary stages of digestion.

They consist of,

1. The Pharynx,
2. The Soft Palate, and
3. The Tongue.

This class of organs, as the term implies, is concerned in swallowing, or conveying the food, after having undergone the process of mastication, and become properly imbued with the salivary fluids, into the esophagus, to be thence conducted into the stomach for the after stages of digestion.

The *Pharynx* (Fig. 36) is a large musculo-membranous bag, opening in front, and situated behind the mouth, the nares, and soft palate. It is connected above by a strong aponeurosis to the cribriform process of the occipital bone, and extends below as far as the fourth and fifth cervical vertebra; behind, it is attached to the bodies of the vertebræ, and laterally, it is connected to the expanded cornua of the hyoid bone.

By these several attachments, it forms a constant and unoccupied cavity, in which may be seen seven openings leading from it, in various directions. The two posterior nares are at the upper and nasal portion; on each side of these, and at the back part of the inferior spongy bones, are the two eustachian tubes leading to the ear. In front and below the velum is the opening into the mouth, and still lower down the openings for the glotti and the commencement of the esophagus.

FIG. 36.

The *Muscles of the Pharynx* are four in number, namely :

1. The Superior—constrictor pharyngis superior.
2. The Middle—constrictor pharyngis medius.
3. Inferior constrictor of the pharynx.
4. Stylo pharyngeus.

The constrictors are seen on the posterior part of the pharynx after removing the cervical vertebræ, and present very much the appearance of one continued sheet of muscle.

The *Superior Constrictor* (*a a* Fig. 36) arises from the cuneiform process of the occipital bone, from the lower part of the internal pterygoid plate of the sphenoid bone, from

FIG. 36. Front view of the muscles of the palate, and posterior portion of pharynx: *a a* Superior constrictor of the pharynx; *b b* Middle constrictor of the pharynx; *c c* Inferior constrictor of the pharynx; *d d* Levator palati; *e* Uvula; *f f* Anterior half arch, containing the constrictor isthmi faucium muscles; *g* Tensor, or circumflexus palati.

the pterygo-maxillary ligament, and from the posterior third of the mylo-hyoid ridge of the lower jaw, near the root of the last molar tooth. It is inserted with its fellow into the middle tendinous line on the back of the pharynx.

The *Middle Constrictor* of the pharynx (*b b* Fig. 36) arises from the appendix and cornu of the os-hyoides, and from the thyro-hyoid ligament; its fibres ascend, run transversely and descend, giving a triangular appearance; the upper ones overlap the superior constrictor, while the lower are beneath the inferior, and the whole pass back to be inserted into the middle tendinous line of the pharynx.

The *Inferior Constrictor* of the pharynx (*c c* Fig. 36) arises from the side of the thyroid cartilage and its inferior cornu, and from the side of the cricoid cartilage, and is inserted with its fellow in the middle line on the back of the pharynx.

This is the largest of the constrictor muscles, and overlaps the constrictor medius.

The action of all these muscles is, to lessen the cavity of the pharynx, and thus compel the food to take the downward direction into the esophagus. The pharynx is lined by mucous membrane.

The *Stylo Pharyngeus* arises from the root of the styloid process, and is inserted into the side of the pharynx and corner of the os-hyoides and thyroid cartilage. It is a large and narrow muscle, and gets to the pharynx between the upper and middle constrictors. Its use is to elevate and draw forward the pharynx, to receive the food from the mouth, also to raise the larynx.

THE SOFT PALATE.

The *Soft Palate* (*e* Fig. 36) is a movable curtain, composed of mucous membrane, enclosing several muscles. It is situated at the back part of the mouth between this cav-

ity and the pharynx, is connected above to the posterior edge of the hard palate, and laterally to the side of the tongue and pharynx.

By this arrangement, the soft palate is made a portion of a lunated or arched form between the cavity of the mouth and the pharynx.

In the centre of this arch an oblong body is suspended, called the uvula, which divides the soft palate into lateral half arches, that pass from the uvula on either side to the root of the tongue.

There is also seen passing from the uvula on each side to the pharynx, two other arches, which, from being behind the first, are called the posterior lateral half arches.

Between the anterior and posterior lateral half arches on either side there is a cavity containing the tonsil glands.

This cavity is the fauces, and the opening between the anterior lateral half arches is the isthmus of the fauces.

The muscles of the palate are four pair, and one single one, namely :

1. The Levator Palati.
2. The Tensor or Circumflexus Palati.
3. Constrictor Isthmi-Faucium, or Palato Glossus.
4. Palato-Pharyngeus.
5. Azygos-Uvulæ is the single muscle.

FIG. 37.

The *Levator Palati* (*b b* Fig. 37) arises from the point of the petrous bone and adjoining portion of the eustachian tube, descends and is inserted into the soft palate. Its use is to raise the palate.

FIG. 37. Posterior view of the muscle of the soft palate: *a* Roof of the mouth or hard palate; *b b* Levator palati; *c* Basilar portion of sphenoid bone; *d d* Eustachian tubes; *e* Tensor or circumflexus palati; *f* Azygos-uvulæ; *g g* Palato-pharyngeus, in posterior half arch.

The *Tensor Circumflexus*, or *Palati*, arises from the base of the pterygoid process of the sphenoid bone, from the eustachian tube, descends in contact with the internal pterygoid muscle, to the hamulus, round which it winds, and is inserted into the soft palate where it expands and joins its fellow. Its office is to spread the palate.

Constrictor Isthmi-Faucium occupies the anterior lateral half arches of the palate; it arises from the side of the tongue near its root, and is inserted in the velum near the uvula.

It draws the velum down and closes the opening into the fauces.

Palato-Pharyngeus occupies the posterior lateral half arches of the palate, and extends from the soft palate behind, near the uvula as its origin, and is inserted into the pharynx, between the middle and lower constrictors and into the thyroid cartilage.

Its use is to draw down the velum and raise the pharynx.

Azygos-Uvulae arises from the posterior spine of the palate bones at the termination of the palate suture, runs along the central line of the soft palate, and ends in the point of the uvula. It raises and shortens the uvula.

It is thus seen that the various muscles of the soft palate are all concerned, more or less, in conducting the food into the pharyngeal cavity. The elevators raise the palate, and at the same time protect the posterior nares from regurgitation of the food, while the tensor puts it on the stretch, and after having passed the velum, the constrictor isthmi-faucium and palato-pharyngeus draw the palate down, and thus close the opening into the mouth, after which the food, as already mentioned, is grasped by the constrictor muscles of the pharynx, and conveyed into the esophagus.

The *Tonsils* are two bodies, each about the size of an almond, seen at the root of the tongue on its side, occupying the cavity between the anterior and posterior half arches. They consist of a congeries of mucous glands, forming somewhat of an oval body, whose enlargement is a frequent obstacle to deglutition, and by their locality near the mouths of the eustachian tubes, a frequent cause of obstruction and deafness.

THE TONGUE.

FIG. 38.

The Tongue is a very complicated organ, for it consists of a great variety of parts, and performs a great variety of functions, and although we have arranged it here as one of the organs of deglutition, it is, nevertheless, a glandular organ, to secrete; a sentient organ, to feel and taste; and, likewise, an intellectual organ, to assist in producing speech.

The tongue is divided into its apex, body and root; the apex is the anterior loose and sharp portion—the root which is thin, is attached to the os-hyoides and is posterior—while the body, which occupies the centre, is thick and broad; it is confined in its situation by reflections of the mucous membrane, to be noticed hereafter.

The upper surface is rough from numerous eminences called the papillæ—which are distinguished into: 1. The

FIG. 38. A front view of the upper surface of the tongue and palatine arch; *a a* Posterior lateral half arches, containing the palato-pharyngei muscles and the tonsils; *b* Epiglottis cartilage; *c c* Ligament and mucous membrane, extending from root of tongue to base of epiglottis cartilage; *d* Foramen cecum or central one of lenticular; *e* Lenticular papillæ; *f* Filiform papillæ; *g* Conical papillæ, scattered over whole surface of the tongue; *h* Point of tongue, *i i* Fungiform papillæ seen on borders of the tongue.

Lenticular ; 2. The Fungiform ; 3. The Conicle ; and, 4. Filliform papillæ.

The *Lenticular* are the largest in size, situated at the root of the tongue, are nine or more in number, and arranged after the manner of the letter A, with the concavity looking forwards.

They are, generally, spherical in shape, and consist simply of mucous follicles like those of the lips, palate, etc. Behind these is observed a depression called the foramen cecum.

The *Fungiform* are next in size, and more numerous; they are found near the borders of the tongue, and present a round head supported on a thin pedicle.

The *Conicle* are still more numerous, and are seen scattered over the whole surface of the tongue, reaching from the lenticular to the apex. They are minute and tapering, and resemble small cones.

The *Filliform* papillæ are the smallest of all, and occupy the intervals between the others, and are also found at the apex of the tongue.

All these papillæ, except the lenticular, from their being so freely supplied with mucous and blood vessels, and having a peculiar arrangement, belong essentially to the function of taste.

The great body of the tongue, however, is muscular in its structure, and its muscles are as follows.

1. The Stylo-Glossus.
2. Hyo-Glossus.
3. Genio-Hyo-Glossus.
4. Lingualis.

These constitute the muscles proper of the tongue. But

there are some others which act more or less indirectly on the tongue and lower jaw. They are

1. The Digastricus.
2. The Mylo-Hyoideus, and
3. The Genio-Hyoideus.

The *Stylo-Glossus* arises from the point of the styloid process and stylo-maxillary ligament. It is inserted into the side of the tongue near its root, its fibres running to the tip.

The *Hyo-Glossus*—a thin, broad, quadrilateral muscle, has its *origin* from the body, cornu, and appendix, of the os-hyoides, and is *inserted* into the side of the tongue, forming the greater part of its bulk.

FIG. 39.

The *Genio-Hyo-Glossus* is a triangular muscle, situated on

FIG. 39. Lateral view of tongue and its principal muscles: *a* Mastoid process; *b* Coronoid process; *c* Stylo-glossus muscle; *d* Hyo-glossus muscle; *e* Genio-hyo-glossus muscle; *f* Genio-hyoid muscle; *g* Section of lower jaw at symphysis; *h* Styloid process.

the inside of the last, and having its *origin* from the upper tubercle on the posterior symphysis of the lower jaw, and its insertion into the body of the os-hyoides and the whole length of the tongue from its base to its apex. The fibres of this muscle radiate in various directions through the tongue.

The *Lingualis* has its *origin* on the under surface of the tongue, extending from its base to the apex, and so intermingling with the other muscles as to be considered rather a part of them than a distinct one.

The *Digastricus*, as its name implies, consists of two bellies united in the middle by a tendon which passes through the stylo-hyoid muscle, and is attached to the hyoid bone. Of the two bellies, the one is posterior, and occupies the fossa at the end of the mastoid process of the temporal bone—the other is anterior, and extending from the os-hyoides to the base of the lower jaw by the side of the symphysis.

The *Mylo-Hyoideus* forms the floor of the mouth and is a broad plane of muscular fibres, having its *origin* from the myloid ridge on the posterior surface of the inferior maxilla, and its *insertion* into the body of the os-hyoides.

The *Genio-Hyoideus* is a short, round muscle beneath the last, and has its *origin* from the lower tubercle on the back of the symphysis of the lower jaw, and *insertion* into the body of the os-hyoides.

All these muscles, by their separate or combined action, have the power of throwing the tongue into every possible variety of position and motion as concerned in the functions of deglutition, suction and speech. They can elevate, depress or turn the tongue to either side; they can protrude it from the mouth or draw it back to the pharynx—make

its upper surface or dorsum either convex or concave, and, finally, can turn the tip, as is well known, either upwards, downwards, backwards or laterally.

THE MUCOUS MEMBRANE LINING THE MOUTH.

The whole interior cavity of the mouth, palate, pharynx and lips, are covered by mucous membrane, forming folds or duplicatures at different points, called *fræni* or bridles. Beginning at the margin of the lower lip, this membrane can be traced lining its posterior surface, and from thence is reflected on the anterior face of the lower jaw, where it forms a fold opposite the symphysis of the chin, the *frænum* of the lower lip; it is now traced to the alveolar ridge, covering it in front, and passing over its posterior surface, where it enters the mouth. Here it is reflected from the posterior symphysis of the lower jaw to the under surface of the tongue, where it forms a fold or bridle called the *frænum lingue*. It now spreads over the tongue, covering its dorsum and sides to the root, from whence it is reflected to the epiglottis, forming another fold; from this point it can be followed, entering the glottis and lining the larynx, trachea, etc.

In the same way, commencing at the upper lip, it is reflected to the upper jaw, and at the upper central incisors forming a fold, the *frænum* of the upper lip; from this it passes over the alveolar ridge to the roof of the mouth, which it completely covers, and extends as far back as the posterior edge of the palate bones; from this it is reflected downwards over the soft palate, or, more strictly speaking, the soft palate is formed by the duplicature of this membrane at this point, between the folds of which are placed the muscles of the palate already described.

From the palate it is traced upwards and continuous with the membrane lining the nares, and downwards with the same lining the pharynx, esophagus, stomach and intestinal canal.

The mucous membrane, after entering the nostrils and lining the roof, floor, septum nasi, and turbinated bones, enters the maxillary sinus between the middle and lower spongy bones, and lines the whole of this great and important cavity of the superior maxilla.

Many mucous glands or follicles, already enumerated, are scattered over the whole of this membrane, and furnish the mouth with its mucus.

As this membrane passes over the superior surface of the alveolar ridge of both jaws, its texture becomes changed, and receives the name of gums.

THE GUMS.

The gums are composed of thick, dense, mucous membrane, adhering to the periosteum of the alveolar processes, and closely surrounding the necks of the teeth, where they are reflected upon themselves, forming a free border or margin, presenting a scalloped or festooned appearance. The longest portions are situated in the interdental spaces between the teeth. The reflected portion unites with the periosteum of the roots at the necks of the teeth, and becomes continuous with it. The texture of the gums differs materially from that of the membrane of which they are composed. Externally, it is very similar to this membrane, but internally, it is fibro-cartilaginous. The gums, when in a healthy state, vary in thickness from one-third to three-fourths of a line.

The gums are remarkable for their insensibility and hardness in the healthy state, but exhibit great tenderness, upon the slightest injury when diseased.

In the infant state of the gums, the central line of both dental arches present a white, firm, cartilaginous ridge, which gradually becomes thinner as the teeth advance, and in old age, after the teeth drop out, the gums again resume somewhat their former infantile condition, showing, "second-childhood."

The gums being endowed with a high degree of vascularity, indicate very correctly, as the author has stated in another part of the work, the state of the constitutional health.

THE ALVEOLO-DENTAL PERIOSTEUM.

This membrane may be properly noticed here, as it is considered by some as continuous with the gums. It lines the *alveolar cavities* or sockets of the teeth, covers the roots of each—is attached to the gums at the necks, and to the blood-vessels and nerves where they enter the roots of the teeth at their apices; and, further, Mr. Thomas Bell believes it is traced into the cavities of the teeth, forming their lining membrane, and continuous with, or the same as that of, the pulp.

The original sac for the pulp has been stated in another place to consist of two membranes, an outer and an inner; these are attached to the gums, and when the teeth come through these membranes and the gums, the remaining part of the sac, especially its outer coat, is supposed by some to constitute the alveolo-dental periosteum, and to be continuous with the gums—while, on the other hand, Mr. Bell believes both membranes of the sac wholly absorbed, and that the true alveolo-dental periosteum is the same as the periosteum covering the upper and lower maxillary bones, and continues into the alveolar cavities, lining their parietes, and thence reflected on the roots of the teeth.

It matters little whether this membrane be a continuation of the gums, the remains of the pulp sac, or the extension of the periosteum of the maxillary bones into the alveolar cavities, since the great practical truth still remains the same, that there is a membrane lining the alveolar cavities and investing the roots of the teeth, and that this membrane is fibrous, and constitutes the bond of union between the alveolar cavities and the roots of the teeth.

The *Dental Ligament*, so recently discovered by a dentist, formerly of Virginia, but now of Philadelphia, as attached to the necks of the teeth, and confirmed, I am sorry to add, by Dr. Goddard, bears no more resemblance to true ligament than the nails do to bone. It consists of the fibres that unite the alveolar to the dental periosteum, and which, according to the last named gentleman, "are very numerous just at the margin of the alveolus."

CHAPTER FIFTH.

BLOOD-VESSELS OF THE MOUTH.

THE arteries that supply the mouth come from the external carotid. This is a division of the common carotid which

FIG. 40.

FIG. 40. A view of the arteries supplying one side of the mouth and face : *a a* External carotid artery ; *b* Inferior maxillary bone with the anterior plate removed so as to expose the roots of the teeth and the inferior dental artery ; *e* Posterior mental foramen, through which the inferior dental artery passes ; *d* Anterior mental foramen, where the same artery comes out to supply the muscles of the lower lip ; *e e* Superior maxillary bone with the lower part of the anterior and outer wall removed, showing the arteries going to the roots of the teeth and cavity of the antrum ; *f* Infra-orbital foramen, through which passes the infra-orbital artery ; *h* Nasal process of superior maxillary bone ; *i* Pterygoideus internus muscle ; *j* Angle of inferior maxillary bone ; *k* Orbit of the eye ; *l* Superior thyroid artery ; *m m* Facial artery ; *n* Terminating branch of the lingual artery ; *o* Termination of

arises on the right from the arteria-innominata, and on the left from the arch of the aorta—after passing up the neck on either side along the course of the sterno-cleido mastoid muscles, it divides on a level with the top of the thyroid cartilage into its two great branches—the external and internal carotid arteries.

The *Internal Carotid Artery* has a tortuous course, is first to the outside and behind the external carotid—then ascends in front of the vertebral column by the side of the pharynx and behind the digastric and styloid muscles to the foramen caroticum in the petrous portion of the temporal bone—thence it traverses the canal in this bone and enters the brain, supplying it with the most of its vessels, not giving any to the mouth.

The *External Carotid* (a a Fig. 36) extends from the top of the larynx to the neck of the condyle of the lower jaw; it is at first anterior and to the inside of the internal carotid, soon gets to the outside, then passes under the digastric and stylo-hyoid muscles and lingual nerve, becomes imbedded in the parotid gland, and finally terminates at the point indicated in the temporal and internal maxillary arteries.

The branches of this artery supply all the organs belonging to the four primary stages of digestion, namely, those of *Prehension*, *Mastication*, *Insalivation* and *Deglutition*.

ARTERIES OF PREHENSION.

These belong, principally, to the lips, and come chiefly from the facial artery.

The *Facial Artery* is the third branch of the external carotid. It ascends to the submaxillary gland, behind

external carotid into the temporal and internal maxillary branches; *p* Temporal artery; *q* Internal Maxillary artery; *r r* Inferior dental artery; *s* Deep temporal branch; *t* Transverse artery of the face; *u u* Muscular branches; *v* Alveolar branch; *w* Posterior dental branch; *x* Terminal branch of infra-orbital artery; *y* Nasal branch of the facial; *z* Submental branch.

which it passes on the bone of the lower jaw—thence it goes in front of the masseter muscle to the angles of the mouth, and, finally, terminates at the side of the nose by anastomosing with the ophthalmic arteries.

In its course it gives off the submental, inferior labial, superior and inferior coronary arteries, which mainly supply the elevators, depressors, and circular muscles of the mouth, those agents concerned in the first steps of digestion—the prehension of the food.

ARTERIES OF MASTICATION.

These come from the internal maxillary and the temporal—the two terminating branches of the external carotid.

The *Internal Maxillary Artery* commences in the substance of the parotid gland—then goes horizontally behind the neck of the condyle of the lower jaw to the pterygoid muscles, between which it passes, and then proceeds forwards to the tuberosity of the superior maxillary bone; from thence it takes a vertical direction upwards between the temporal and external pterygoid muscles to the zygomatic fossa, where it again becomes horizontal, and, finally, ends in the speno-maxillary fossa by dividing into several branches.

Those branches of the internal maxillary supplying the passive organs of mastication, or the superior and inferior maxillary bones, with the teeth, are,

1. Inferior Maxillary or Dental Artery,
2. The Alveolar or Superior Dental,
3. The Infra-Orbital,
4. The Superior Palatine, and
5. The Spheno-Palatine.

The *Inferior Dental Artery* enters the posterior mental foramen of the lower jaw, passes along the dental canal beneath the roots of the teeth—sending up a twig through

the aperture of each to the pulps of the teeth as it passes along, and, finally, escapes at the anterior mental foramen on the face—a branch of it, however, continues forwards to supply the incisors.

The *Superior Dental Artery* winds around the maxillary tuberosity from behind forwards, sending off twigs through the posterior dental canals which supply the molars, and go to the maxillary sinus—while the main branch is continued forward, furnishing the gums.

The *Infra-Orbital Artery* enters the infra-orbital canal, traverses its whole extent, and comes out at the foramen of the same name, upon the face; just before it emerges it sends down the anterior dental canal a twig for the incisors and cuspidati.

The *Superior Palatine* descends behind the superior maxillary bone, passes through the posterior palatine canal to the roof of the mouth, and supplies the palate, gums and velum pendulum palati. It also sends off a small branch through the foramen incisivum to the nose.

The *Spheno-Palatine* entering the back part of the nose through the spheno-palatine foramen, is distributed upon the pituitary membrane.

The arteries supplying the *active organs of mastication*—the temporal, masseter, and pterygoid muscles, are,

The temporal, anterior and posterior deep—the pterygoid and masseteric branches of the internal maxillary artery—while the *temporal artery*, which is the other terminating branch of the external carotid, gives off the middle temporal artery, to the temporal muscle, and a branch, the transverse artery to the masseter.

The *Temporal Artery* begins in the substance of the parotid gland at the neck of the condyle of the lower jaw, mounts over the zygoma in front of the meatus, and ascends about

an inch or more when it divides into its anterior and posterior branches.

ARTERIES OF INSALIVATION.

These belong to the salivary glands. The parotid is supplied by the posterior auricular, a branch of the external carotid, and by the transverse artery of the temporal. The submaxillary is supplied by the facial and the sublingual by a branch of the lingual artery.

ARTERIES OF DEGLUTITION.

The pharynx, soft palate and tongue, are the organs supplied by these arteries.

The *Arteries of the Pharynx* are the superior and inferior pharyngeal and inferior palatine.

The superior is a branch of the internal maxillary, and is spent upon the upper part of the pharynx, and sends a branch through the pterygo-palatine foramen to supply the arch of the palate and contiguous parts. The inferior is a branch of the external carotid, and in its course upwards towards the basis of the cranium, it sends several branches to the pharynx and contiguous deep-seated parts. The inferior palatine is given off by the facial.

The *Arteries of the Soft Palate* are,

The superior palatine, inferior palatine, and inferior pharyngeal branches.

The *Superior Palatine* comes off from the internal maxillary behind the orbit in the pterygo-maxillary fossa, descends in the posterior palatine canal, comes out on the back part of the roof of the palate through a foramen of the same name, and proceeds inwards and forwards, supplying the soft palate and mucous membrane.

The *Inferior Palatine* is a branch of the facial, and passes up between the stylo-glossus and stylo-pharyngeus muscles to the tonsil and soft palate. It also anastomoses with the superior palatine branch of the internal maxillary artery. The inferior pharyngeal is a branch of the external carotid.

The *Arteries of the Tongue* are the *Lingual*. These arteries, on either side, arise from the external carotid, run forwards above and parallel with the os-hyoides—then ascend to the under surface of the tongue as far as the tip, under the name of the *ranine* arteries. They give off numerous branches in their course, supplying every part of the tongue.

The mucous membrane of the mouth is principally supplied by the anterior and posterior palatine, and facial arteries. The gums by the alveolar and submental branches.

The *Branches* of the *External* carotid artery as they arise in numerical order, are as follows :

1. The Superior Thyroid.
2. The Lingual.
3. The Facial.
4. The Inferior Pharyngeal.
5. Occipital.
6. Posterior Auricular.
7. Temporal.
8. Internal Maxillary.

The internal maxillary, being the great artery of the mouth, gives off branches in the following order :

- | | | |
|---|---|---|
| Origin behind the neck
of the Condyle. | { | <ol style="list-style-type: none"> 1. A Tympanic Branch, 2. Inferior Dental, 3. The Greater Meningeal, 4. Lesser Meningeal. |
|---|---|---|

Origin between Ptery- goid Muscles.	{	5. Posterior Deep Temporal Artery, 6. Masseteric, 7. Pterygoid Arteries.
Origin Zygomatic fossa.	{	8. Buccal Artery, 9. Anterior Deep Temporal, 10. Alveolar or Superior Dental, 11. Inferior Orbital.
Origin Spheno-Maxil- lary fossa.	{	12. Pterygoid or Vidian, 13. Superior Pharyngeal, 14. Superior Palatine, 15. Spheno-Palatine Artery.

THE VEINS.

The veins correspond so nearly, both in name and course with the arteries, that a description of them would be only a repetition of what has been said ; suffice it, therefore, to observe, that there are two veins to every artery, and that they are mostly collected into a common trunk at the angle of the jaw, called the external jugular vein, which passes down the neck in the course of the fibres of the platysma muscle, and terminate in the subclavian vein at the posterior edge of the sterno-mastoid muscle.

The office of the veins is to return the blood back to the heart.

CHAPTER SIXTH.

THE NERVES OF THE MOUTH.

THE nerves supplying the mouth belong to the fifth pair, and the portio-dura of the seventh or facial nerve.

FIG. 41.

FIG. 41. The fifth nerve with its branches: *a* The inferior maxillary bone; *b* Posterior dental foramen where the inferior dental nerve enters to supply the teeth; *c* Inferior dental nerve; *d* Gustatory branch of fifth nerve; *e* Muscular branch of inferior maxillary nerve; *f* Ophthalmic nerve; *g* Infra-orbital foramen where infra-orbital nerve comes out; *h* Terminating branches of inferior dental nerve; *i* Casserian ganglion; *j* Internal view of maxillary sinus; *k* Superior maxillary nerve, just where it is given off from the ganglion; *l* Posterior dental branch of superior maxillary nerve; *m* Anterior branch of superior dental nerve; *n* Terminating branches of infra-orbital nerve; *o* Nasal branch of ophthalmic nerve; *p* Frontal branch of ophthalmic nerve.

The *Fifth* (Trigemini) are the largest of the cranial nerves, and give sensibility to all the organs concerned in the primary stages of digestion.

This nerve will also be found to be a compound nerve, having also motor filaments, and thereby giving motion as well as sensation.

It is first seen at the side of the pons varolii near its junction with the crura-cerebelli—but its origin is much deeper and further back.

It arises by two fasciculi which can be traced down to the spinal chord, and coming from its anterior and posterior ends. It is hence considered a spinal nerve, and as such called the cranial spinal nerve.

These two fasciculi, the one anterior and the other posterior, constitute the fifth nerve, which consists of eighty or one hundred filaments that pass forwards and outwards in a canal formed of dura mater to a depression on the anterior surface of the petrous bone.

At this point it spreads into a ganglion, called the Casserian ganglion, on the under surface of which is seen the anterior root, but having no connection with the ganglion, and can be traced on, as will be presently shown, to the inferior maxillary nerve.

From the ganglion of Casser proceed three primary branches, namely :

1. The Ophthalmic.
2. Superior Maxillary.
3. Inferior Maxillary Nerves.

The *Ophthalmic Nerve* is a short trunk that goes into the orbit through the foramen lacerum superius, and divides into three principal branches,

1. The Frontal,
2. The Lachrymal, and
3. The Nasal.

The *Frontal* passes along the roof of the orbit to the

supra-orbital foramen, through which it passes, and is then called the supra-orbital nerve, and is spent on the muscles and integuments of the forehead. It gives off several branches in its course.

The *Lachrymal*, as the term implies, goes to the lachrymal gland, taking the outward direction, and sending branches in its course to the upper eye-lid, conjunctiva and other parts.

The *Nasal* takes its direction along the inner side of the orbit to the anterior ethmoidal foramen, through which it passes into the cranium, on the upper surface of the cribriform plate of the ethmoidal bone, descends by the side of the crista-galli through a slit-like opening into the nose, and there terminates by filaments, which are spent upon the septum, mucous membrane, anterior nares, etc. It sends off several branches in its course, one in particular to the lenticular ganglion at the bottom of the eye, others to the caruncula lachrymalis, lachrymal sac, conjunctiva, etc., but as these do not belong to the mouth and dental apparatus, we will pass to the second great division of the fifth.

THE SUPERIOR MAXILLARY NERVE.

This nerve proceeds from the middle of the Casserian ganglion, passes through the foramen rotundum of the sphenoid bone, into the pterygo-maxillary fossa; here it enters the canal of the floor of the orbit—the infra-orbital canal, traverses its whole extent, and emerges on the face at the infra-orbital foramen, where it terminates in numerous filaments in the muscles and integuments of the upper lip and cheek.

The superior maxillary nerve supplies the upper jaw, and gives off many important branches, which are as follows:

In the pterygo-maxillary fossa two branches descend to a small reddish body called the ganglion of Meckel, or the

spheno-palatine ganglion, situated on the outer side of the nasal or vertical plate of the palate bone.

From this ganglion proceed three branches :

1. An Inferior, Descending, or Palatine Nerve.
2. An Internal, Lateral Nasal, or Spheno-palatine.
3. A Posterior, Pterygoid, or Vidian.

The *Palatine Nerve* descends through the posterior palatine canal, comes out at the posterior palatine foramen along with an artery of the same name, and supplies with filaments the soft palate, uvula, tonsils, the roof of the mouth, and the inner alveoli and gums.

The *Lateral Nasal* enters the nose through the spheno-palatine foramen, divides into several filaments, which enter the mucous membrane covering the upper and lower turbinated bones, and one long branch can be traced along the septum nasi as far as the foramen incisivum, where it meets the anterior palatine branches in a ganglion called the naso-palatine.

The *Vidian*, or *Pterygoid*, passes backwards from the ganglion of Meckel through the pterygoid canal at the root of the pterygoid process—then enters the cranium through the foramen lacerum anterius, and divides into two branches, one of which enters the carotid canal and unites with the sympathetic branches of the superior cervical ganglion—thus connecting this ganglion with the ganglion of Meckel.

The other, the proper vidian nerve, enters the vidian foramen or hiatus fallopii on the petrous bone, joins the portio-dura nerve, accompanies this as far as the back part of the tympanum, then leaves it, enters the cavity of the tympanum, and receives here the name of *Chorda Tympani*. It leaves this cavity, after supplying the several parts, by the glenoid fissure, now joins the gustatory nerve, continues with it to the submaxillary gland, where it parts and is lost in the submaxillary ganglion, situated at the posterior part of the submaxillary gland.

This exceedingly intricate course of the vidian nerve is interesting from the number of communications which it establishes between different and distant parts, for it unites the ganglion of Meckel with the superior cervical ganglion of the sympathetic, and both with the submaxillary ganglion—it also connects the superior and inferior maxillary nerves to one another and the portio-dura.

The *Superior Maxillary Nerve* gives off next in the sphenomaxillary fossa :

1. The Orbital.
2. The Posterior Dental Nerve.

The *Orbital* enters the orbit through the sphenomaxillary fissure, and then sends off a *malar* and *temporal* branch, which pass out through the malar bone, the first supplying the cheek, the latter accompanying the temporal artery to the integuments of the side of the head.

The *Posterior Dental Nerves*, three or four in number, descend on the tuberosity of the superior maxillary bone, and enter the posterior dental canals to supply the molar teeth ; one branch penetrates the antrum and courses along the outer wall, anastomosing with the anterior dental nerves—while another runs along the alveolar border supplying the gums.

The superior maxillary nerve now enters the infra-orbital canal, and becomes the *infra-orbital nerve*, which is its terminating branch.

The *Infra-Orbital* nerve comes from behind forwards through the canal of the same name, and gives off no branch until it arrives at the forepart, where it sends down along the front of the maxillary sinus in the anterior dental canal the *anterior dental nerve*, which divides so as to supply the incisors, cuspidati and bicuspidi, also the mucous lining membrane of the antrum.

This nerve now emerges, as before mentioned, at the infra-orbital foramen, between the levator labii superioris alæque nasi and levator anguli muscles, dividing here into many branches, some of which ascend to the nose and eyelids, others pass downwards and outwards to the lip and cheek, anastomosing with the nasal branch of the ophthalmic and the facial branches of the portio-dura.

INFERIOR MAXILLARY NERVE.

This nerve forms the third great division of the fifth. It is the largest branch, and passes from the ganglion of Casser through the foramen ovale of the sphenoid bone to the zygomatic fossa.

This nerve as stated, is united to the anterior or motor root, which come together on the outside of the foramen ovale. then in the zygomatic fossa, the inferior maxillary nerve divides into two branches :

1. An External, or Superior.
2. An Internal, or Inferior.

The *External* is the motor branch, and gives off the following filaments to the several muscles :

1. *Masseteric*, crossing the Sigmoid notch to the Masseter Muscle.
2. *Temporal*, Anterior and Posterior Deep to the Temporal Muscle and Fascia, &c.
3. *Buccal*, to the Buccinator, &c.
4. *Pterygoid*, to the Pterygoid Muscles.

The *Internal* division of the inferior maxillary nerve consists of three branches, all of which give sensation, and are :

1. The Anterior Auricular.
2. The Gustatory.
3. The Inferior Dental.

The *Anterior Auricular* passes behind the neck of the

lower jaw and in front of the meatus of the ear, and ascends through the parotid gland, over the zygoma along with the temporal artery, and divides into anterior and posterior branches.

In its course it unites with the facial nerve, and supplies the parotid gland, the articulation of the lower jaw, the meatus, and cartilages of the ear and side of the head.

The *Gustatory Nerve*, immediately after its origin, sends a branch to the inferior dental; it then descends between the pterygoid muscles, where the chorda tympani joins it; it now passes along the ramus of the lower jaw, covered by the internal pterygoid muscle, then above the submaxillary glands, and forwards above the mylo-hyoid and between it and the hyo-glossus muscles, accompanied by the duct of Wharton, and finally ascends above the sublingual gland to the lateral, inferior and anterior parts of the tongue.

In its course, MR. HARRISON enumerates the following branches as given off by this nerve:

“First, one or two small filaments to the internal pterygoid muscle. Second, several to the tonsils, to the muscles of the palate, to the upper part of the pharynx, and to the mucous membrane of the gums. Third, the chorda tympani, and some accompanying filaments to form a plexus, which supplies the submaxillary gland. Fourth, a few branches which descend along the hyo-glossus muscle to communicate with the ninth or lingual nerve. Fifth, a fasciculus of nerves to the sublingual gland and to the surrounding mucous membrane. Lastly, at the tongue it divides into several branches, some pass deep into the tissue of this organ, others along, firm and soft, rise towards its surface, and are lost in the mucous membrane and in a small conical papilla near its tip.”

The *Inferior Dental Nerve* passes between the pterygoid muscles, then along the ramus of the lower jaw under the

pterygoideus internus to the posterior mental foramen which it enters along with an artery and vein ; it now traverses the inferior dental canal, sending off twigs into all the roots of the molars and bicuspid. Opposite the anterior mental foramen it divides into two branches, the smaller is continued forward in the substance of the jaw to supply the roots of the cuspidati and incisors—while the larger comes out at the mental foramen, is distributed to the muscles and integuments of the lower lip, and, finally, communicates with the facial nerve.

The inferior dental, just as it enters the posterior dental foramen, gives off the *mylo-hyoid* nerve ; this passes forwards in a groove of the lower jaw, and supplies the mylohyoid, genio-hyoid and digastric muscles.

THE FACIAL NERVE.

FIG. 42.

The *Portio-dura* of the seventh or facial nerve, is the last nerve to be noticed as particularly belonging to the mouth.

The *Facial Nerve* arises from the medulla oblongata between the corpus olivare and restiforme, close by the lower margin of the pons varolii ; it then passes forwards and outwards with the portio-mollis, to the foramen auditorium internus, which it enters and passes on to the base

FIG. 42. View of the facial nerve, or portio-dura of the seventh pair : *a* Trunk of the facial nerve ; *b* Ascending branch ; *c* Descending branch ; *d* Posterior auricular branch ; *e e* Temporal branches ; *f f* Malar branches ; *g g* Inferior maxillary branches ; *h* Posterior or great occipital nerve ; *i* Terminal branches of the inferior dental nerve ; *j* Terminal branches of infra-orbital nerve ; *k k* Supra-orbital nerve and its branches ; *l* Orbicularis oris ; *m* Zygomaticus major ; *n* Zygomaticus minor ; *o* Levator labii superioris alaeque nasi ; *p* Orbicularis palpebrarum ; *q* Depressor anguli oris.

of this opening ; here these two nerves separate, the mollis going to the labyrinth of the ear—while the facial enters the aqueduct of Fallopius, where it is joined by the vidian ; it then goes in a curved direction outwards and backwards behind the tympanum, where it parts with the vidian, and proceeds on to the stylo-mastoid foramen, at which it emerges. At this point it sends off three small branches :

1. The Posterior Auricular.
2. The Stylo-Hyoid.
3. The Digastric.

The *Posterior Auricular* ascends behind the ear, crosses the mastoid process to the occipito-frontalis muscle.

The *Stylo-Hyoid* is distributed to the stylo-hyoid muscle.

The *Digastric* is distributed to the posterior belly of the digastric muscle.

The facial nerve being deeply imbedded in the substance of the parotid gland, divides into two branches, the one is superior, the other inferior ; these two have frequent unions called the *pes anserinus* or *parotidean plexus*, and send branches to the whole of the side of the face.

The upper branch, called the temporo-facial, ascends in front of the ear upon the zygoma, accompanies the temporal artery and its branches, supplying the side of the head, ear and forehead, and anastomosing with the occipital and supra-orbital nerves ; a set of branches pass transversely to the cheek, furnishing the lower eyelid, lips, side of the nose, and uniting with the infra-orbital nerve.

The inferior or cervico-facial branch descends, supplying the lower jaw and upper part of the neck, giving off the following branches :

1. The Maxillary.
2. The Submaxillary.
3. The Cervical.

The *Maxillary* passes the ramus of the jaw and masseter muscle to the lower lip and its muscles.

The *Submaxillary* courses the base of the lower jaw, supplying the muscles which arise from this part, and both anastomosing with the mental nerve.

The *Cervical* are long and numerous, and go to the platysma and superficial muscles of the neck, uniting with branches from the cervical plexus.

The facial is the great motor nerve of the face. Mr. Bell calls it a respiratory, and thinks it chiefly concerned in expressing the passions.

In consequence of the numerous communications which this nerve has with other nerves, the name of *Sympatheticus Minor* has been given to it by some anatomists.

Having now very briefly described the anatomical elements of the several organs of the mouth, it may be well to notice, in conclusion, the anatomical and physiological relations of this cavity.

ANATOMICAL RELATIONS OF THE MOUTH.

The mouth has many interesting anatomical relations with the rest of the body, a few of which it may be well to mention.

By means of its lining mucous membrane it is connected through similar continuity of structure with the stomach and the whole of the intestinal canal, etc.

Disease still further establishes this structural relation. Inflammation, ulceration, or any other anatomical change in the stomach or intestines is felt and reported on the tongue, gums and other parts of the mouth, showing the sympathy and the close anatomical relationship of these several parts.

The mouth is also connected by the same mucous mem-

brane with the organs of respiration by being continued down into the larynx, trachea and bronchia.

By the fifth pair of nerves, the mouth, and especially the dental apparatus, has a most important relation with the brain, nervous system, and all the parts dependent on them.

Simple irritation from teething has frequently thrown children into convulsions—and in adults tooth-ache often creates extreme irritability of the whole nervous system. But it is not necessary to dwell here on the morbid sympathies of the mouth with other parts of the body, as the author will have occasion to do this in other parts of the work. It will be well, however, to mention in this place that there is a general anatomical relation of the mouth with the rest of the body, by means of the blood-vessels and cellular tissue.

These latter are the most pervading general elements of the body; they are found every where connecting and binding together all the organs in one great and common family, and in this manner the mouth is related to and forms an essential link in this natural chain.

PHYSIOLOGICAL RELATIONS.

The mouth has been shown to consist, not only of a great variety of parts, but, also, that it has an equally great variety of functions.

The functions of the mouth have been stated to be those of prehension, mastication, insalivation and deglutition.

These functions, it has been seen, are all closely related the one with the other, and mutually dependent; and how beautiful is the harmony of action as well as its regular and orderly succession. We see in the first place the prehensile instruments laying hold of and introducing the food into the mouth—then the organs of mastication, the teeth and upper and lower jaw bones, put into operation by the

temporal, masseter and pterygoid muscles, grind it down into minute portions, which at the same time is formed into a bolus by being mixed with the salivary fluids, furnished by the parotid, submaxillary and sublingual glands; then it is taken by the organs of deglutition, namely, the tongue, palate and pharynx, and passed by these into the esophagus, to be thence conducted into the stomach—thus demonstrating the harmony of relation among the several functions belonging to the mouth.

But the functional relation of the mouth is no more confined to itself than its structural relation; the one is equally commensurate with the other; and as the structure of the mouth has been shown to be continuous with, and to extend to the most extreme parts of the body, so we find that the functions of the mouth equally involve all the great, general and leading functions of the body.

For example, if the primary stages of digestion be impaired or improperly performed in the mouth, the whole process of digestion must also be, necessarily, imperfect; the stomach will form bad chyme, the intestines bad chyle, and this impure fluid will go to the heart and lungs where bad blood will be formed, and as a necessary consequence, the functions of circulation, respiration and innervation, will also become implicated, and in this way we see, that by disturbing only one link, at once the brotherhood of the great functional chain becomes broken.

Again, the mouth is intimately related with the intellectual functions; as for instance, that of speech. Who does not know that when any of the teeth are wanting, the palate cleft, or there is a hare-lip, how much the speech is impaired? And so with all the other functions of the body, the relation between them and the mouth, and the mutual dependence of each on the other, is equally demonstrable.

The *Formation* and *Progress* of the teeth, might seem to come most naturally under consideration in this place, but we defer their description for the next chapter, to which the reader is referred.

CHAPTER SEVENTH.

ORIGIN AND FORMATION OF THE TEETH.

OF all the operations of the animal economy, none are more curious or interesting than that which is concerned in the production of the teeth. In obedience to certain developmental laws, established by an all-wise Creator, it is carried on from about the sixth or seventh week of intra-uterine existence, with the nicest and most wonderful regularity, until completed, and so secretly conducted as to prevent the closest scrutiny from detecting the manner in which it is effected; enough, however, is ascertained from its progressive results to excite in the mind of the physiologist the highest admiration.

From small mucous papillæ, observable at a very early period of fetal life, situated in a groove, lined with mucous membrane, and running along the alveolar border of each jaw, the teeth are gradually developed. As they increase in size, they assume the shape of the crowns of the several classes of teeth they are respectively destined to produce. Having arrived at this stage of their formation, they now begin to dentinify first upon the cutting edges of the incisors, the apices of the cuspidati, bicuspidis and eminences of the molars; from thence the process is continued over the whole surface of their crowns, until they become invested in a complete layer of dentine: and so on, layer after layer is formed, one within the other, until the process of solidification is completed. But before it has progressed very far, the enamel and roots of the teeth begin to form, and these formative operations, including dentition, are gone through with previously to the completion of the dentification of the pulps.

In the meantime, and in anticipation of the loss of the temporary teeth, a second set is forming, and as the teeth of the one are removed, they are promptly replaced by those of the other. Thus, by this beautiful and most admirable provision of nature, the first set of teeth intended to subserve the wants only of childhood, while the jaws are too small for the reception of such as are required for an adult, are removed, and replaced by a larger, stronger and more numerous set.

The elder writers, regarding a knowledge of the early stages of the development of the teeth as not of much importance, paid little attention to the subject, and hence, this most curious and interesting department of developmental anatomy has remained, until recently, measurably uncultivated. EUSTACHIUS, we believe, was the first to notice the position and arrangement of the teeth in the jaws previously to their eruption. But his researches were confined to the examination of the jaws after birth, at which period he speaks of having discovered, by dissection, the incisors, cuspidati and three molars on each side in each jaw, partly in a gelatinous and partly in a solidified condition. He also discovered the incisors and cuspidati of the permanent set behind the first.

Eustachius wrote in 1563, and nineteen years later, URBAN HEMARD, a French anatomist and surgeon, although unacquainted with the work of the former, gave a very similar description of the situation of the crowns of the incisors and cuspidati of both sets in the jaws of an infant at birth. He represents them as partly bony and partly mucilaginous. He also discovered the bicuspidi, but he was unable to find the molars at so early a period as birth.

The researches of ALBINUS threw no additional light upon the manner of the formation of the teeth, and little was known concerning the earlier stages of the development of these organs until the time of John Hunter, who informs us that in the alveoli of a fetus of three or four months, "four or five pulpy substances, not very distinct, are seen."

But he says, "about the fifth month the alveolar cavities are more perfect and the pulps of the teeth more distinct," and that the anterior are more advanced than those further back in the jaws. It is at about this age that he dates the commencement of dentinification on the edge of the temporary incisors. The situation and arrangement of the teeth in the jaws at this period he describes very accurately. At the expiration of the sixth or seventh month, he represents the first permanent molar as having begun to be formed in the tubercle of the upper jaw, and "under and on the inside of the coronoid process in the lower," and he states, that the pulps of the permanent central incisors begin to appear in a fetus of "seven or eight months," and to dentinify "five or six months after birth." The pulps of the permanent lateral incisors and cuspidati he says begin to be formed soon after birth; the first bicuspid about the fifth or sixth year, the second bicuspid and molars the sixth or seventh, and the *dentes sapientiae* about the twelfth year.

Although Mr. Hunter gives a more minute and accurate description of the progress of the formation and arrangement of the teeth in the jaws previously to their eruption than any previous writer, yet with regard to their origin and appearance during the earlier stages of their development, it is unsatisfactory. Nor do the researches of Jourdain, Blake, Fox, Cuvier, Serres, Delabarre and other writers, throw much additional light upon the subject. In fact, they could not, as their researches do not seem to have been commenced at periods sufficiently early in fetal subjects; and even from the time when they were first instituted, the progress of the organs do not appear to have been traced through the subsequent stages of their formation with the requisite degree of care and accuracy. It is not, therefore, necessary to notice the description given by these authors of the progress of the formation of the teeth, although it may not be amiss to state here, that Dr. Blake describes the rudiments of the permanent as originating from the sacs of the temporary, and that this supposed discovery has been

confirmed by almost every subsequent writer upon the subject.* Indeed, until quite recently, this has been the prevailing opinion, and their progress, step by step, from the time when the rudiments of these teeth are apparently given off as small bud-like processes from the sacs of the temporary, is traced with a degree of minuteness by Mr. Thomas Bell, that would seem to preclude the possibility of deception. This last named gentleman describes the process as commencing at a very early period of the formation of the temporary teeth, and as first perceivable "in a small thickening on one side of the parent sac," which, "gradually increasing," becomes "more and more circumscribed, until it at length assumes a distinct form, though still connected with it by a peduncle, which," he says, "is nothing more than a process of the investing sac." "For a time," continues Mr. Bell, "the new rudiment is contained within the same alveolus with its parent, which, excavated by the absorbents for its reception, by a process almost unparalleled in the phenomena of physiology. It is not produced by the pressure of the new rudiment, as is erroneously believed, but commences in the cancelli of the new bone immediately within its smooth surface, thus constituting what may be termed a process of anticipation. The new cell after being sufficiently excavated, and as the rudiment continues to increase, is gradually separated from the former one, by being more and more deeply excavated in the substance of the bone, and also by the deposition of a bony partition between them; and at length the new rudiment is shut up in its proper socket, though still connected with the temporary tooth by a chord or process of the capsule already described, which has in the meantime been gradually attenuated and elongated.†"

* It is said, but with how much truth the author is unable to say, that this supposed discovery was made about twenty years before the publication of Dr. Blake's Inaugural Dissertation, by a French dentist by the name of Herbert.

† This chord has been noticed and minutely described by several other writers. Delabarre calls it the appendage of the dental matrix, and traces it through what

Now it would hardly seem possible for a man of Mr. Bell's accuracy of observation, after having investigated the subject as closely and thoroughly as he must have done, to have enabled him to describe so minutely the various stages of the progress of the development of the permanent teeth, to have mistaken their origin, and that he has, would appear, by subsequent researches, to be rendered certain. I allude to those of ARNOLD and GOODSIR.

The last named author has traced the progress of the teeth, almost from the moment of the appearance of the germs of the first set, as simple mucous papillæ, until the completion of the second, and so minutely and accurately, that little remains to be done by future anatomists, for the perfection of this branch of odontology.

Relying upon the accuracy of his researches, which are described, at length, in the *Edinburg Medical and Surgical Journal*, for January 1st, 1839, we shall proceed to give a brief summary of their result, as the length of the paper is such as to preclude its insertion entire.

FIG. 43.

They were commenced in an embryo at the sixth week, at which period a deep groove, formed by two semi-circular folds, extending around each jaw, is perceived, lined with mucous membrane and as this gradually widens from behind forwards, a ridge, commencing posteriorly and running in the same direction, rises from its floor, and divides the original groove into two others; the outer one forming the duplicature of mucous membrane from the inside of the lip to the outside of the alveolar process, the inner one constituting what may

is usually denominated the alveolo-dental canal, which he designates by the name of *iter dentis*, to the surface of the gum behind the temporary teeth. He also states that it is hollow, and when he first described it in his thesis of reception in 1806, it had not been noticed by any other writer.

FIG. 43. Upper jaw of human fetus at sixth week; a The lip; b Primitive dental groove.

be very properly denominated the *primitive dental groove*, as the germs of the teeth appear in it.

The inner lip of the inner groove is formed by the outer edge of a semi-circular lobe which is to constitute the future palate. By the seventh week after conception, the germ of the first temporary molar in the upper jaw may be seen in the *primitive dental groove*, rising up from the mucous membrane lining its floor in the form of a *simple free granular papilla*, of an ovoidal shape—the long diameter of which is antero-posterior. By the

FIG. 44.

eight week, another papilla, of a rounded and granular form is observable, between the middle and anterior curve of the ridge, on the floor of the same groove, which is the rudiment of the temporary cuspidatus. During the ninth week, the germs of the incisors—the central first, and soon after the lateral—make their appearance in the form also of mucous papillæ. During the tenth week the sides of the groove before and behind the anterior molar papilla have been gradually approaching each other and processes from its sides are sent off, from before and behind this germ, which meet and enclose it in a follicle. In the meantime a similar follicle is gradually forming around the cuspid germ. Towards the end of the tenth week, the papilla of the second or posterior temporary molar shows itself.

The papillæ of the incisor teeth, which, up to this time, have advanced very slowly, now begin to increase more rap-

FIG. 44. Lower jaws of human fetus at the ninth week of intra-uterine life, taken from Kölliker; magnified nine diameters: *a* Tongue thrown back; *b* Right half of the lip depressed; *c* Left half cut off; *d* Outer alveolar wall; *e* Inner alveolar wall; *f* Papilla of the first molar; *g* Papilla of the cuspidatus; *h* Of the second incisor; *i* Folds where the *ductus riviniani* subsequently enter.

idly, and during the eleventh and twelfth weeks, processes are sent off from the outer and inner walls of the groove, forming for each a distinct follicle, and while the papillæ of the cuspidatus and first molar are now undergoing little change, that of the second molar is gradually increasing. During the thirteenth week a follicle is formed for it, and a gradual change takes place in the different papillæ; each begins now to assume a particular shape—the incisors, that of the future teeth—the cuspidati “become simple cones,”—the molars “become flattened transversely.” The papillæ now “grow faster than the follicles, so that the former protrude from the mouths of the latter while the depth of the latter varies directly as the length of the fangs of their future corresponding teeth.” The mouths of the follicles, in the meantime, are becoming more developed, “so as to form opercula, which correspond in some measure with the shape of the crowns of the future teeth.” Of these, the incisor follicles have two—one anterior and one posterior—the first larger than the latter; the cuspidati follicles have three—one external and two internal; the molar follicles, as many as there are eminences or tubercles upon the grinding surfaces of these teeth.

The outer and inner lips of the primitive dental groove have increased so much, that at the fourteenth week, they meet and come themselves together like two valves, so as to give the papillæ the appearance of receding back into their follicles, and to become almost wholly hid by their opercula. The appearance and progress of the germs of the lower teeth and their follicles are nearly precisely similar to those of the upper, though they do not appear at quite so early a period.

At the epoch last mentioned, the primitive dental groove is situated on a higher level than at first, contains the germs and follicles of the ten temporary teeth, and “may now be more properly denominated the *secondary dental groove*,” for it is about this time, that provision is made for the production of the ten anterior permanent teeth. It consists in

the appearance of a depression of a crescent shape immediately behind the inner opercula of the follicles ; first, of the central incisors, next of the laterals, then of the cuspids, afterwards of the first bicuspid. The opercula, in the meantime, close the mouths of the follicles, but without adhering ; beginning with the central, then with the lateral, the cuspidati, and ending with the second molars. The secondary groove is now soon closed by the approach and adhesion of its lips and walls, commencing from behind and proceeding forwards—changing the follicles into sacs—the papillæ into the pulps of the temporary teeth, and the crescent-formed depressions into “*cavities of reserve*” from which the pulps and sacs of the teeth of replacement are developed. The *primitive dental groove*, which, by this time, has extended itself back of the second temporary molar, still retains its original appearance ; it has a grayish yellow color, and its edges continue “smooth for a fortnight or three weeks longer” for the development of the papilla and follicle” of the first permanent molar.

The papillæ of the temporary teeth are now gradually moulded into the shape of the teeth they are destined to form : the pulps of the upper molars are perforated by three canals, and the lower by two, which penetrate to their centre. The primary base is divided into an equal number of secondary bases, from which the roots of the future teeth are gradually developed. An intervening space is now formed between the pulps and the sacs, by the more rapid growth of the latter than the former, “in which is deposited a gelatinous granular substance, at first small in quantity, and adherent only to the proximal surfaces of the sacs, but ultimately, about the fifth month, closely and intimately attached to the whole interior of these organs, except for a small space of equal breadth, all round the base of the pulps, which space retains the original gray color of the inner membrane of the follicle, and as the primary base of the pulp becomes perforated by the canals formerly mentioned, the granular matter sends processes into them, which ad-

hering to the sac, reserve the narrow space described above, between themselves and the secondary bases. These processes of granular matter do not meet across the canals, but disappear near their point of junction." The granular matter, although not adhering to the pulp, is exactly moulded to all its eminences and depressions.

The outer membrane of the sac, according to Mr. Good-sir, is supplied with blood from small twigs sent off by each branch of the dental artery at the fundus of its destined sac, and from the arteries of the gums, which inosculate with each other, and then ramify the "true" (inner) membrane.

The follicle of the first permanent molar closes about this time, and has granular matter deposited in its sac, and by the non-adhesion of the walls of the secondary groove, a cavity appears below the sac of this tooth, and from the lining mucous membrane the second and third molar teeth derive their origin.

But previously to this period, the apices and eminences of the temporary teeth have become vascular, and now earthy salts begin to be deposited. Simultaneously with this process, the inner surface of the granular matter is absorbed, and after a while becomes so thin as to render the subjacent vascularity apparent. This goes on, and by the time a layer of dentine has formed over the whole surface of the pulp and reached its base, no remains of it are left.

The cavities of reserve have been gradually receding and assuming a position behind the temporary teeth, the distal extremities of the anterior ones begin to distend about the fifth month, and it is here that the germs of the teeth of replacement first appear, and are indicated by a bulging up or folding of this portion of these cavities. These soon acquire the appearance of dental pulps, and the mouths of the cavities gradually become obliterated.

By the sixth month, bony septa have formed across the alveolar groove, and niches are now formed on the posterior walls of the alveoli for the sacs of the permanent teeth.

The sac of the first permanent molar remains up to the eighth, and even the ninth month, imbedded in the maxillary tuberosity. The roots of the temporary incisors, at or a little before birth, begin to be formed, and in the accomplishment of which, says Mr. Goodsir, "three cotemporaneous actions are employed, viz. the lengthening of the pulp; the deposition of tooth substance upon it; and the adhesion of the latter of that portion of the inner sac which is opposite to it." By this time the central incisors appear through the gum, the jaw has lengthened so much, that the first permanent molar begins to assume its proper position in the posterior part of the alveolar arch. The sacs of the permanent teeth continue to recede during the advance of the temporary teeth and their sockets to acquire their perfect state, and to insinuate themselves between the sacs of the former until they are only connected by their proximal extremities, through the alveolo-dental foramina or *itinera dentium* of Delabarre.

The vessels which go to the sacs of the permanent teeth are derived, first, from the gums, but they ultimately, receive vessels from the temporary sacs, which, uniting with the others, eventually retire into permanent dental canals.

The following diagram, taken from Goodsir, exhibits at one view the origin and progress of the formation of a temporary and its corresponding permanent tooth.

FIG. 45.

FIG. 45. *a* Mucous membrane; *b* Mucous membrane, with a granular mass deposited in it; *c* The primitive dental groove; *d* A papilla on the floor of the groove;

The cavity of reserve, behind the first permanent molar, begins to lengthen about the seventh or eighth month, a papilla soon appears in its fundus, it then contracts and separates from the remainder of the cavity, by which means a new sac is formed, that of the second permanent molar. As the jaw increases in length, it comes downwards and forwards. The papillæ of the wisdom teeth (*dentes sapientiæ*) form in the remaining portion of the cavities of reserve, which, in the upper jaw, occupy the maxillary tuberosities, and in the lower, the base of the coronoid processes, which places, says Goodsir, they do not leave until the nineteenth or twentieth year.

The progress of the formation of the three molar teeth, will be seen in the diagram, Fig. 46, also copied from Mr. Goodsir.

From the foregoing generalization of the description given by Mr. Goodsir of the development of the pulps and sacs of the human teeth, it is seen, that the papilla of the first temporary molar makes its appearance at about the *seventh week* of embryonic life; at the *eighth week*, the cuspid papilla is developed: during the *ninth*, the papillæ of the incisors make their appearance, and by the end of the *tenth week*, the papilla of the second temporary molar may be

e The papilla enclosed in a follicle, and the secondary dental groove forming; *f* The papilla assuming the shape of a pulp, the opercula forming, and a depression for a reserve cavity behind the inner operculum; *g* The papilla becomes a pulp, the follicle a sac by the adhesion of the lips of the opercula, and the secondary dental groove in the act of closing; *h* The secondary groove adherent, except behind the inner operculum, where it has left a shut cavity of reserve for the formation of the pulp and sac of the permanent tooth; *i* The last change more complete by the deposition of the granular body, deposition of tooth substance commencing; *j* The cavity of reserve receding; its bottom, in which the pulp is forming, dilating; *k* The cavity of reserve becoming a sac with a pulp at its bottom, and further removed from the surface of the gums. The temporary tooth covered with a layer of bone, and the granular substance absorbed; *l* The temporary tooth acquiring its root and approaching the surface of the gums; *m* Root of the temporary tooth longer, and its sac touching the surface of the gum; *n* Eruption of temporary tooth, its sac again a follicle, and the permanent receding further from the surface of the gum; *o* Completion of temporary tooth, free portion of sac become the vascular margin of the gum, and the permanent sac connected by a cord passing through the alveolo-dental canal or foramen.

seen. At the end of the fourteenth week, the primitive dental groove, containing the germs and follicles of the ten temporary teeth, and situated on a higher level, becomes the secondary dental groove, from which the papilla of the teeth of replacement are furnished. The secondary groove assuming the form of crescent-shaped depressions behind the palatine opercula of the follicles of the temporary teeth. The cavities of reserve for the permanent teeth gradually recede and assume a position behind the sacs of the deciduous teeth. From the distal extremities of these the papilla of the replacing teeth are developed.

FORMATION OF THE DENTINE.

With regard to the manner of the formation of the dentine, odontologists do not agree. Mr. Thomas Bell is of the opinion that it is secreted by the external surface of the membrane which immediately invests the pulp, designated by Raschkow, the *preformative membrane*, the pulp serving only as a mould upon which this substance is formed. Purkinjé and Schwann believe that the pulp is converted into dentine by a transition process, the superficial cells upon the surface assuming first, an elongated form, corresponding in diameter and direction with the fibres of the dentine; or, in other words, that the dentine is formed by the dentinification of the pulp.

Professor Owen maintains that it is by "*centripetal calcification* of the pulp's substance." He says, "in the cells of the dentinal pulp the nucleus fills the parent cell with a progeny of nucleoli before the work of calcification," more properly, dentinification, begins. Again, "the primary cells and the capillary vessels and nerves are imbedded in, and by a homogeneous, minutely subgranular, mucilaginous substance. The cells which are smallest at the base of the pulp, and have large, simple, subgranular nuclei, soon fall into linear series, directed towards the periphery of the pulp: where the cells are in close proximity with that periphery, they become more closely aggregated, increase in size, and present the following changes in their interior. A pellucid point appears in the centre of the nucleus which increases in size and becomes more opaque around the central point, rendering the compressorium requisite for its demonstration. A division of the nucleus in the course of its long axis is next observed. In the larger and more elongated cells, still nearer the periphery of the pulp, a subdivision of the nuclei has taken place, and the subdivisions become elongated with their long axis vertical or nearly so to the plane of the pulp, and to the field of cal-

cification. The subdivided and elongated nuclei become attached by their extremities to the corresponding nuclei of the cells in advance; and the attached extremities become confluent. Whilst these changes are proceeding, the calcareous salts of the surrounding plasma begin to be accumulated in the interior of the cells, and to be aggregated in a semi-transparent state around the central granular part of the elongated nuclei, which now present the character of secondary cells, and the salts occupy, in a still clearer and more compact state, the interspaces of such cells; the elongated granular matter of the terminally confluent secondary cells establishes the area of the tubes, by resisting, as it would seem, the encroachment of the calcareous salts; the nuclear tracts receiving a similar proportion of the salts, in the condition of minute disintegrated particles, which are usually arranged in a linear series of nodules, and contribute to cause the white color of the moniliform area of the tube, when viewed by reflected light, and its opacity when viewed by transmitted light. Thus the primitive existence of the granular nuclei, their multiplication in the primary or parent cell, their elongated form, their serial arrangement end to end, and terminal confluence, are indicated in the calcified pulp by the area of the dentinal tubes; the interspaces of the metamorphosed nuclei being occupied by calcareous salts in a clearer and more compact state, with evidence, however, of a distinctness of the nucleolar membrane or secondary cell from the cavity of the common containing cell, which sustains the interpretation of the proper parietes of the dentinal tube. The indications of the primitive boundary or proper parietes of the parent cell are in like manner more or less distinctly retained, through a modification of the arrangement of the calcareous salts in the boundaries and in the interspaces of the cells." The foregoing is but a small part of the description given by this learned writer, but enough to show his views upon this intricate operation of the economy.

FIG. 47.

Mr. Alexander Nasmyth says, "the cells of the pulp are converted into ivory" (dentine) "cells by the deposition within them of earthy salts, and the cells so converted, with their nuclei, are the perfect ivory; moreover, the nuclei assume a peculiar arrangement and constitute the structure which I have described and demon-

strated by the name of baccated fibres." This explanation of the manner of the formation of dentine, designated by Mr. Nasmyth by the name of ivory, differs but little from that given by Professor Owen.

The changes which the pulp undergoes a little before and at about the time of the commencement of the deposition of earthy salts is described more clearly by Mr. Tomes than by any preceding writer. He divides the development of the pulp into three stages. The first, he terms the *areolar*; the second, the *cellular*, and the third, the *linear* stage. The first embraces the period of the earliest appearance of the pulp; the second, from the time when it is composed of nucleated cells and a subgranular uniting medium to the

FIG. 47. A diagram copied from Mr. Nasmyth's work on the Development, Structure and Diseases of the Teeth, showing the vascular and cellular structure of the pulp of a tooth, and the conversion of the cells into dentine. *a* "The blood-vessels and capillaries of the pulp, between which the cellular structure is seen." *b* "The cells in process of conversion into ivory," or rather dentine, "and occupying the peripheral portion of the pulp." "In the line between *c c*, the transition of these cells into the structure of ivory," or dentine, is more clearly exhibited.

period when the former begins to assume a linear arrangement, which arrangement, immediately precedes dentinification, and constitutes the third stage.

FIG. 48.

FIG. 49.

The cells nearest to the coronal surfaces are the first to assume this position. The columns thus formed of the cells take an arrangement nearly vertical to

the coronal surface, or corresponding to the direction of the dentinal tubes or fibres of the perfected tooth, and running parallel to each other. Scarcely any trace of the areolar tissue seen in the first or earlier stage can be detected in this or the second stage.

These three conditions, in the advanced pulp, are not distinguished according to Mr. Tomes, by well defined lines of demarcation, "but are beautifully blended, the one with the other, passing from the one extreme of condition to the other so gradually that the transitions are not at first recognized, and when fully recognized are again lost in the gradations towards a further change."

The cells decrease in size from the surface toward the central portion of the pulp, but the smaller increases to the size of the larger when the time for their dentinification arrives. Each cell after falling into line, divides into two or more in its length, and each division elongates. A central nucleus or open space is seen in each cell, which lengthens with the cell. The cells by their increased length become placed end to end, and ultimately unite; and the elongated central space of each individual, by a further de-

velopment, joins and opens into those of the super-imposed cells; thus forming a central tube common to the linearly united cells," as seen in Fig. 50.

FIG. 50.

period of development the earthy matter is received into the cellular or rather tubular and intertubular tissue, whereby the gelatinous matrix, having assumed the required form, is converted into tubular and intertubular tissue; in other words into dentine. In some instances the linearly arranged cells have two or even three central cavities, but in the progress of development they become joined in one. Sometimes they appear empty, at other times occupied by granular matter. In either case they are usually described under the name of nuclei." The transparent structureless membrane enclosing the pulp is the first to undergo solidification.

Professor Kölliker entertains very nearly the same opinion with regard to the manner of the formation of dentine as that expressed by Mr. Tomes. After advancing three hypotheses, he concludes by expressing the belief, that the matrix of the dentinal tubes, the intertubular tissue, "proceeds from the cylindrical cells investing the pulp of the tooth, which undergo a greater or less elongation, coalesce and ossify." The canaliculi, or tubes, he believes, arise, either from the nuclei of these cells, or are, which he believes to be more probable, the remains of the cavities of the cells, the boundaries of which having undergone greater consolidation, and, therefore, correspond with lacunæ of bone. The divisions, he thinks, may be owing to a longitudinal division, from time to time, of the cells, or by the union of one cell with two.

FIG. 50. The pulp in the third stage, showing the cells placed end to end and becoming confluent; also, two lines of cells uniting to form one.

The foregoing brief summary of the opinions of the authors referred to, will serve to convey a tolerably correct idea of the views at present entertained with regard to the manner of the formation of dentine.

FORMATION OF THE ENAMEL OF THE TEETH.

The opinion formerly entertained upon this subject was, that the enamel is a deposition from the inner membrane of the dental sac; that this, after the surface of the pulp of the tooth has dentinified, pours out upon it a thick fluid, which soon condenses, assuming at first a chalky appearance, and, afterwards, by a process somewhat similar to crystallization, attains the glossy-like hardness by which it is characterized. The author was for a long time of this opinion, but recent observations, strengthened by a perusal of the thesis of RASCHKOW, have led him to believe it erroneous.

The gelatinous granular substance mentioned by Goodsir, and called by Raschkow the adamantine organ, situated between the follicle and tooth germ—the latter of which it invests, at first loosely, but afterwards more closely, moulding itself to the pulp, there is good reason to believe, is destined for the formation of the enamel. It is represented by the last named author as forming a globular nucleus between the follicle and dental germ at a very early period of the growth of the latter, with a bulging externally, and presenting a parenchymatous appearance internally; but gradually exhibiting angular granulations, held together by filaments of cellular tissue, resembling “a kind of actinenchyma, such as may be seen in plants.” It was the discovery of this granular substance in dissecting the jaws of a pig that first induced the writer to suppose the old doctrine of the formation of the enamel to be incorrect. It is at first as represented by Raschkow and Goodsir, disconnected from the dental germ, surrounded by fluid, bearing a striking resemblance to the liquor amnii, but is gradually transformed into a membrane, and as dentinification com-

mences in the pulp, attaches itself to it, and adheres with considerable tenacity.

It was no doubt the discovery of this that led Delabarre to suppose the enamel an integral part of the tooth and proceeding from the dental embryo, for he speaks of the formation of this outer coating of the teeth as being produced by an immense number of small exhalent vessels which formed a sort of imperceptible velvet. Into these he believed the phosphate of lime was deposited, and in such a way as not to destroy their organic sensibility.

Raschkow says, "The dental germ, in advancing further and further into the dental follicle, makes first only a slight impression on the globular mass of the enamel organ, but this impress is rendered gradually deeper as the growth of the germ proceeds. When the germ has penetrated further into the hollow thus made, it appears narrower towards the base, and thicker under the apex, and is enclosed around on every side by the parenchyma of the enamel-organ, which thus assumes the appearance of a hood, covering the dental germ when advanced in its development, and capable of being separated from it without difficulty, and without injury, either by the compressor, or in any other manner, by being placed under water." He also represents it as being disconnected from the dental capsule, except at the coronal portion, where it seemed to be united by some loose vessels; it is thus that he accounts for the numerous capillaries which pervade the parenchyma of the organ; and from this, he assumes that while the dental germ has its origin from the extremity of the sac next the root, the enamel-organ originates from the opposite or coronal extremity, and that arising at opposite points, they "approach each other, are adapted together, and both contribute to the production of the tooth."

After the enamel-organ has adapted itself to the dental pulp, a peculiar organ is seen on its inner surface, consisting of short uniform fibres placed perpendicularly "to the cavity, and forming, as it were, a silky lining" to it,

which, in a transverse section of the enamel-organ, may be "clearly seen, and can be accurately distinguished from the other stellated parenchyma of the substance" which Raschkow designates the enamel pulp.

According to this author, this stratum of fibres, originating in "the transformation of the pulp of the enamel," with which it is for a time connected, afterwards separates from it, so as only to adhere by "a few filaments of cellular tissue; and becomes a genuine membrane;" this, on account of the function it performs, he styles the enamel membrane. "Its inner surface consists of hexangular, nearly uniform, corpuscles, visible only through a magnifying glass; towards the centre of each of which is a round eminence. These corpuscles are nothing more than the ends of short fibres, of which the whole membrane is composed; and which being pressed together, assume freely the hexangular form." These he describes as being disposed in regular series, and corresponding with the arrangement of the enamel fibres.

Each of these fibres is an excretory duct or gland, whose peculiar function it is to secrete the "enamel fibre corresponding to it." Immediately after the commencement of dentinification of the pulp, each one of these fibres, with its inner extremity placed upon the now forming subjacent dentine, begins to secrete the earthy salts of which this substance is chiefly composed. While this is going on, an organic lymph seems to be secreted from the parenchyma of the enamel-membrane which penetrates between the individual fibres, and renders their whole substance soft. This, by means of a "chemico-organic process," afterwards combines with the earthy substances, and forms the animal base of the enamel.

It has been shown by Raschkow, that the dental pulp is invested by a very delicate membrane, which he denominates the *preformative membrane*, and there is every reason to believe, that this constitutes the bond of union between the enamel fibres and the dentine of the tooth.

Admitting this theory of the formation of the enamel to be correct, the frame work of animal tissue, spoken of by Mr. Nasmyth, as entering into the composition of this substance, is readily accounted for. In no other way, except the theory of Delabarre be correct, and this is by far the most plausible, can its presence be satisfactorily explained.

With regard to the manner of the formation of *Nasmyth's membrane*, Professor Kölliker inclines to the opinion that it is "a calcified, amorphous exudation, secreted from the enamel organ immediately after the ossification of the last enamel cells, which glues together and protects the ends of the prisms of the enamel." Huxley, on the other hand, believing the enamel to be formed beneath the membrane which invests the pulp, called by Raschkow the *preformative membrane*, is of opinion that Nasmyth's membrane is merely an altered condition of this. His theory, however, of the manner of the formation of the enamel prisms, as well as of the membrane in question, lacks conformation. That part which relates to the formation of the enamel fibres, is little more than a revival of the theory of Delabarre.

FORMATION OF THE CEMENTUM, OR CRUSTA PETROSA.

The manner of the formation of the cementum, has been variously explained. Raschkow conjectures that it is probably produced by the remains of the enamel pulp. More recent writers seem to regard the cemental pulp as a production of the dental sac, but the writer is inclined to believe that it is a production of that portion of the preformative membrane which invests the elongated part of the pulp destined for the formation of the root, and that this, as earthy salts are deposited in the pulp, pours out a blastema in which nucleated cells are developed. He was led to the adoption of this belief from an examination of a tooth, on every part of the surface of which, there is a development of exostosis. Such development is now universally admitted to be a hypertrophied condition of cementum, the structure of the former being identical with the latter.

The tooth in question belongs to the Museum of the Baltimore Dental College,* and the development of the exostosis must have commenced simultaneously with the commencement of the deposition of earthy salts in the dentinal pulp, and so rapidly did it proceed, that it completely broke up the enamel organ, penetrating every part of it, so that only here and there, imbedded in its substance, small patches of enamel are seen. This phenomenon can only be accounted for by supposing that the investing membrane of the pulp, from some inexplicable cause, poured out a blastema, which was immediately converted into cementum, and that this took on a hypertrophied condition before, or simultaneously with, the deposition of earthy salts in the cells of the fibres of the enamel organ.

* It was presented to the Author, for this institution, by Dr. Swayze,

CHAPTER EIGHTH.

FIRST DENTITION.

THE crowns of the temporary teeth, as has been shown, are solidified and coated with enamel at birth, and although at about this period the roots of the incisors begin to be formed, yet they still occupy their bony cells in the alveolar ridge. But, as the time approaches when the system requires a diet better suited to the support of its increasing energies than milk, the one on which the child has hitherto subsisted, nature, as if conscious of the change about to take place, calls into action certain agents, by which the openings in the alveolar cells are enlarged, and through which, in obedience to an established law, the little gems, sparkling with whiteness, gradually and slowly emerge, pair after pair, until the pearly arches are completed, to answer the demands of increasing wants, and to assist in the articulation of those lisping accents, by which the child's early wishes are made known.

Dentition is divided by Mr. Goodsir, into three stages, namely, the *Follicular*, the *Sacular*, and the *Eruptive*. The two first have already been considered, and it now only remains to treat of the last.

ERUPTION OF THE TEMPORARY TEETH.

Various opinions have been advanced with regard to the manner in which the passage of a tooth, from the alveolus through the gum, is effected. Some suppose it is the result of the elongation of the pulp for the formation of the root; others, that it is a consequence of the moulding of the alve-

olus around the latter, as it is formed. Some believe that the opening through the gum is effected by the mechanical action of the coronal extremity of the advancing tooth; others, and with far more plausibility of reason, that it is the result of the action of absorbent vessels.

The able physiologist and learned dentist, Delabarre, has advanced a most ingenious theory upon this subject. He believes that the passage of a tooth through the gum, or rather its escape from its matrix, is effected in precisely the same manner as is the birth of a child. He regards the sac, the gums forming one point of attachment for it, and the neck of the tooth the other, as the chief agent, and believes that it is by the contraction of this, that the latter is raised from the bottom of the alveolus, and ultimately forced through the dilated orifice of the former and gums.

This is the most rational theory that has been advanced; it explains, upon principles of sound physiology, this most wonderful and curious operation of the economy. It is difficult to imagine how the elongation of the pulp, or the moulding of the alveolar walls to it, can have any agency in forcing the tooth through the gums. If the elongation of the pulp commenced before the crown of the tooth had made any advance towards the gums, it would at once come in contact with the floor of the alveolus, and in its soft and yielding condition, be caused to assume a configuration different from that presented by the root of a naturally developed tooth. The crown of the tooth, therefore, must make some progress towards the gum, before the elongation of its pulp can commence, and it is difficult to conceive how this can be effected, if it is not by the contraction of the sac.

This theory is objected to by some, on the ground that the two membranes of which the dental matrix or sac is composed, are of a fibrous structure, and consequently, not endowed with contractile properties; but the microscope of Mr. Nasmyth, has shown that the inner lamina is composed of layers of cells, loosely arranged, and separated by interspaces equal to half the diameter of the cell. In another

place, the same writer observes, that the inner lamina seems to partake more of the nature of a serous than of a mucous membrane. That the sac does contract, is proven by the fact, that it shortens as the tooth advances, so that, ultimately, after the complete extrusion of the crown, it constitutes the free edge of the gum.

The dentinification of the exterior of the root of the tooth proceeds nearly as fast as the elongation of the pulp for its formation. Commencing at the neck, it proceeds inwards and downwards, forming concentric layers, one within and above the other, until it reaches the extremity, and nothing remains but a small canal running through the centre, from its apex to the cavity in the crown, through which the dental vessels and nerves pass. The alveolus, in the meantime, deepens; its walls approach each other, and closely embrace the root of the tooth.

As soon as the edge of the coronal extremity of the tooth comes through the gum, the sac assumes its primitive follicular condition, but still connected with the neck of the tooth, it continues to contract until the whole of the crown has emerged from the gum.

The periods of the eruption of the temporary teeth is variable, depending probably upon the state of the constitutional health. The following, however, may be regarded as a very near approximation, namely:

The central incisors from 5 to 8 months after birth.

“ lateral incisors	“ 7 to 10	“ “ “
“ first molars	“ 12 to 16	“ “ “
“ cuspidati	“ 14 to 20	“ “ “
“ second molars	“ 20 to 36	“ “ “

No general rule, however, can be laid down from which there will not be frequent variations. The following is the most remarkable case of deviation, not only from the most usual period, but also from the natural order of the eruption of the teeth which the author has ever met with. In November, 1846, he was sent for to lance the gums of an infant only four months old. On examining the mouth, the

gums on each side, both in the lower and upper jaws, about where the first temporary molars are situated, were found much swollen and inflamed. As these teeth were evidently forcing their way through the gums, and as the child was threatened with convulsions, it became necessary to lance them immediately. This was accordingly done, which gave instant relief to the little sufferer. In a few days after, the teeth made their appearance, but the eruption of the central incisors did not take place until about the seventh month.

There is sometimes an extraordinary tardiness of action in the eruption of the temporary teeth. There is a case of a child, somewhere on record, that did not get any of its teeth until it was ten years old. Lefoulon states that he saw a young girl of seven years of age, whose inferior incisors had not appeared. Several cases have come under the observation of the author in which dentition did not commence until the fifteenth, and one not until the twentieth month. On the other hand, there are cases of precocity of action in the eruption of the teeth equally remarkable, as for example, when the two lower incisors are erupted at birth; such occurrences have been met with. Louis XIV was born with four teeth, and Polydorus Virgilius mentions a child that was born with six. Haller, in his *Elements of Physiology*, enumerates the cases of nineteen children who were born with teeth. Other examples are on record, and there are few physicians or dentists who have been in practice ten or fifteen years, who have not met with like cases.

In speaking of those early productions, Mr. Fox says, "As they only have a weak attachment to the gums, they soon get loose, producing a considerable inflammation in the mouth of the child, as well as occasioning considerable inconvenience to the mother. It is, therefore, advisable to extract them immediately, for they can never come to perfection." The author is compelled to differ with Mr. Fox, for their attachment is not always, as he supposes, confined to the gums; their roots are sometimes securely fixed in

sockets in the jaw. When this is the case, they seldom occasion much inconvenience, and their extraction would be highly improper. It is always better, therefore, to wait until there is some positive indication that such operation is necessary, before performing it.

In the eruption of the teeth, nearly the same order is followed that is observed in their solidification. The central incisors appear first, then the lateral, next the first molars, afterwards the cuspidati, and, lastly, the second and third molars.

The lower teeth in their eruption, are said, usually, to precede the upper about two or three months, but the upper appear first nearly as often as the lower.

MORBID EFFECTS RESULTING FROM FIRST DENTITION.

When we consider the early age at which first dentition commences, and the fragile and irritable state of the system, it will not appear wonderful that infants should so frequently suffer from the efforts of the economy for the liberation of these organs from the bony cells and superincumbent gums, in which they are confined. The constitution, at this tender period of life, often receives a shock from which it never recovers; and the seeds of many chronic diseases are caused to germinate, which, otherwise, in all probability, would have forever remained dormant.

This is generally regarded as the most critical period of life, and it has often proved one of bereavement and sorrow. The whole process is sometimes completed without inconvenience, but, at other times, it is attended with so much pain and irritation that the most alarming and complicated forms of disease result from it.

The irritation accompanying first dentition is supposed to be caused by the pressure which the teeth make upon the gums in forcing their way out, which irritation varies in extent, according to the health and temperament of the child. When the absorption of the gums and dilatation of the neck

of the sac keep pace with the growth of the tooth, the pressure is scarcely perceptible; but when these functions are tardily performed it becomes more or less great, in proportion as the growth of the one outstrips the absorption and dilatation of the other. It may be, that much of the irritation is produced by the pressure of the tooth upon the pulp, for, when its progress is retarded by the resistance of the gums, the elongation of this, for the formation of the root, would, of necessity, cause the solidified part to press upon it, which, as a matter of course, would give rise to great pain and irritation.

Dr. Good is of opinion that the pressure of the teeth against the gums "is not uniformly exerted through the course of teething, but is divided into distinct periods or stages as though the vital or instinctive principle, which is what we mean by nature, becomes exhausted by a certain extent of action, and requires rest and a state of intermission.

"The first or active stage of teething is usually about the third or fourth month of infancy, and constitutes what is called breeding the teeth, or the conversion of the pulpy rudiment buried in the gums, and formed during fetal life, into a solid material, which, at the same time, shoots downward, and gives to every tooth a neck or fang."

The period of dentition here referred to is the time when the sac begins to contract. The coronal extremity of the tooth is then brought in contact with the sac, and when the formation of the root of the former proceeds more rapidly than the contraction of the latter, the root comes in contact with the bottom of the alveolus, and doubtless much of the irritation, as we have before intimated, resulting from dentition, is attributable to this circumstance. But Dr. G. is mistaken in supposing that the pulpy rudiment begins to be converted into a solid material, at the third or fourth month of infancy, when, what he terms the first or active stage of teething commences. Several layers of dentine are perfectly formed over most of the pulps of the temporary teeth at

birth, though the enamel is not quite completed at so early a period. The doctor has evidently confounded the commencement of the elongation of the pulp with that of its solidification.

During the period of teething, the child is restless and fretful, but its paroxysms of suffering are periodical, and seldom last more than two or three hours at a time ; whereas, were the pressure of the teeth upon the gums uniform and constant, there would be no intermissions. The repose thus afforded, enables the system to recover in some degree from the exhaustion occasioned by each preceding paroxysm. If it were not for this, its excited energies would soon be worn out, and the child fall a victim to the continued intensity of its sufferings.

When the irritation is merely local, it is usually of short duration, and consists in a slight tenderness and tumefaction of the gums, accompanied by increased secretion of saliva. But when it is sufficiently great to effect the functional operations of other parts of the system, febrile symptoms of a general and more or less aggravated character, supervene, attended with drowsiness, diarrhea, and not unfrequently, with various cutaneous eruptions, as the red gum, and of pustules, at first filled with limpid fluid, but which, afterwards, become purulent. The former appear on the neck and face : the latter are not confined to any particular part of the body, but are either thinly scattered over its whole surface, or appear in small patches. There is also another kind of eruption which breaks out about the mouth, cheeks and forehead, sometimes extending to the scalp, which, in a short time dries up and becomes covered with disagreeable scabs. These drop off, after a while, to be succeeded by others.

These eruptions are generally regarded as indications of the substitution of a milder for a more aggravated form of disease, and should not, therefore, be too hastily suppressed.

To these symptoms, we may add, cough, spasms of the muscles of the face, particularly of those about the mouth,

and, when the diarrhea is so copious as to occasion great emaciation, convulsions and death, sometimes, supervene.

Thus far, we have merely glanced at a few of the effects of first dentition. To attempt a description of all, would involve the enumeration of the whole catalogue of diseases peculiar to infancy, and which, as they more properly belong to another branch of medicine, we shall neither stop to describe nor point out, minutely, their curative indications.

It may be well, however, to state, that the local treatment consists in making a free incision with a lancet through the tumefied gum, down to the advancing tooth. This, in very many cases, affords immediate relief and supersedes the necessity of other treatment. It is objected to by some, on the ground, that, though it may afford temporary relief, the cicatrix formed by the healing of the wound, constitutes a greater obstacle to the exit of the tooth, than the parts ever do when left to themselves. Now, any one at all conversant with the subject, knows that in four cases out of five, where the operation is necessary, the teeth are so far advanced, that when the incised gums collapse, their crowns immediately protrude: and even when the wound does unite, the soft and spongy cicatrix yields more readily to the action of the absorbents than the gums do in their natural state.

Another objection is founded upon the supposition that the enamel, at this early period, is in a soft and amorphous state, and that, consequently, the teeth may be injured by the contact of the knife. But as the parts of the enamel exposed to the instrument usually attain their greatest hardness before such operation is required, this objection is without foundation. In short, we have never known any injury to result from it, either in our own practice, or in that of others: nor can those who are opposed to it, bring facts to support their opposition.

It is true, there is sometimes considerable hemorrhage, which, in two or three instances, has terminated fatally, but it rarely happens that this is very considerable, and it almost always subsides in a few minutes.

This simple operation often succeeds after all others have failed. We have frequently known children, after having suffered the greatest agony for days and weeks, and until they had become reduced to mere skeletons, obtain immediate relief without any other treatment. This at once removes the cause, whereas, other remedies only counteract the effects of the suffering, and can only be considered as palliatives that may assist nature in her struggles with disease, but cannot always prevent her from sinking in the contest.

CHAPTER NINTH.

SHEDDING OF THE TEMPORARY TEETH.

SOME very singular notions were entertained among the ancients concerning the temporary teeth. Many thought they never had roots, inasmuch as they were observed to be wanting when they dropped out; others, that the crowns were removed, while the roots remained and afterwards grew and became the permanent teeth.

This most wonderful operation of the economy is affected in accordance with an established law, but there exists, among physiologists, some difference of opinion with regard to the precise manner in which it is effected. Most writers ascribe their destruction to the action of the absorbents. Mr. Fox supposes, that as the new teeth begin to rise from their sockets, they come in contact with, and press upon, first, the partition of bone intervening between them and the roots of the temporaries, and afterwards upon the roots themselves; and this pressure, he believes, induces their absorption. He afterwards, however, admits that pressure is not necessary to their absorption, as it sometimes takes place where there is none.

Mr. Hunter does not attempt to explain the manner of the destruction of the roots of the temporary teeth in any other way than by stating, that they decay off up to the gum. Fauchard and Bourdet attribute their removal to the action of a corrosive fluid, supplied for the special purpose. Bunon thinks they are worn away by the rising teeth. Lecluse is of the opinion that when the process of their removal begins, their vessels cease to supply nourishing juices, and

that they are broken up by a species of maceration, while Jourdain thinks it is both by abrasion and corrosion.

Mr. Bell, as do indeed almost all recent writers, adopts the theory of Mr. Fox, that the destruction of the roots of the temporary teeth is the result of absorption. Laforgue, observing a fungiform or carneous substance behind the root of the temporary tooth, which, in fact, had been noticed by Bourdet, and supposed by him to exhale a fluid possessed of solvent qualities, gave it the name of absorbing apparel, and assigned to it the office of removing the root of the primary tooth.

Delabarre, who has treated this subject at greater length and, apparently, investigated it more closely, corroborates the views of Laforgue, and gives the following description of the manner of the formation and function of the carneous substance spoken of by this author as the absorbing apparel. "While the crown of the tooth of replacement," says Delabarre, "is only in formation, the exterior membrane of the matrix is simply crossed by some blood-vessels; but as soon as it is completed, the capillaries are then developed in a very peculiar manner, and form a tissue as fine as cobweb; from this tissue the internal membrane, instead of continuing to be very delicate, and of a pale red color, increases in thickness and assumes a redder hue. As was before said, it is at the instant in which commences the contraction of the coats of the matrix, that are conveyed from the gum to the neck of the tooth, that the plaiting of the vessels, that enter into their tissue, compose a body of a carneous appearance, whose absorbents extend their empire over all the surrounding parts; it is, therefore, the dental matrix itself, that, after being dilated to serve as a protecting envelop to the tooth, is contracted to form not only this bud-like body which we find immediately below the milk tooth; at the instant in which it naturally falls out, and whose volume is necessarily augmented as odontocia gradually goes on; but also a carneous mass by which the whole is surrounded, and

whose thickness is the more remarkable as the organ that it envelops is nearer its orifice."

After giving this description, he asks, "Is there a dissolving fluid that acts chemically on the surrounding parts, or do the absorbents, without any intermedial, destroy everything that would obstruct the shooting up of the tooth?" In reply to this, he says, "Not possessing positive proof, suitable to guide me in the decision of this question, and finding those of others of little importance; I shall not attempt to answer them."

In pursuing this subject further, he states that the vessels of the temporary tooth often remain entire in the midst of this carneous (fleshy) substance, continue to convey their fluids to the central parts of the teeth, whilst the calcareous ingredients and the gelatine have been removed, and that, at other times, they too, are destroyed. The conclusion to which he arrives, after a careful examination of the whole subject, is, that whether the earthy and animal parts of the roots are removed by the absorbents of the carneous tubercle in question without any previous change, or whether they are decomposed by the chemical action of a fluid exhaled from it, they are ultimately carried back into the general circulating system.

In proof of the agency of the carneous (fleshy) tubercle in the destruction of the roots of the temporary teeth, he mentions one fact that goes very far to establish the truth of the opinion, and if his views be correct, will account for those cases which are occasionally met with, where one or more of the permanent teeth fail to appear. It is this: if this substance fails to be developed, or is destroyed, the tooth remains in its socket, and never makes its appearance. Cases of this kind have fallen under the notice of almost every dentist.

In as few words as possible we have given the views of this ingenious writer on the subject under consideration, and although they do not seem to have attracted much attention from English writers, and are rejected by Mr. Bell, on the

ground, as he says, but which we have never known to be the case, that the destruction of the root of the temporary frequently commences on a part "the most remote from the sac of the permanent tooth," we are disposed to believe them, for the most part, correct. As to the existence of the fleshy tubercles, there can be no question, and that it is through the agency of these that the roots of the temporary teeth are destroyed, seems more than probable. But, whether it is through the agency of their absorbent vessels or a chemical fluid exhaled for the purpose, may not, as Delabarre says, be so easy to determine. We are inclined to believe, however, that the latter agent is the one principally concerned in effecting their destruction, and for the reason that if litmus paper be applied to the fleshy tubercle, immediately the crown of a temporary tooth has fallen out or been removed, it turns red, thus showing the presence of an acid. That the absorbents have something to do in this operation of the economy, is, we think, very probable, but we believe the operation of these delicate vessels is here always preceded by the action of a chemical agent.

The change that takes place in the external membrane of the sac, as noticed by Delabarre, is observable, first, on the peduncle or chord leading from it to the gum behind the temporary tooth. It here becomes thickened, about the time the root of the new tooth begins to form, and assumes a fleshy appearance, and it is here that the destruction of the surrounding bone commences, enlarging the alveolo-dental canal, and gradually removing the intervening bony partition, and, finally, the root of the temporary tooth. The agency of this thickened and fleshy condition of the exterior membrane of the capsule, in the removal of the roots of the temporary teeth, is rendered more conclusive by the fact, that, in those cases where the roots of the permanent teeth have become partially destroyed, the alveolo-dental periosteum presents a similar appearance. In the formation, too, of alveolar abscess, the tubercle at the extremity of the root presents a like aspect. There also seems to be, in this in-

teresting operation of the economy, an association of functions mutually dependent upon each other, so that, if one be suspended, the others fail to be performed. Thus, if from any cause, the sac fails to contract, the fleshy tubercle is not developed, nor does the formation of the root take place—consequently, the crown of the tooth remains in its alveolus. Harmonious consent of associated actions are nowhere more beautifully exemplified, than in these three operations of the economy.

It often happens, that the root of a temporary tooth fails to be destroyed, and that the crown of the replacing organ comes through the gum in a wrong place. Whenever this occurs, the carneous body is developed only beneath the parts through the opening of which the new tooth has appeared, and is not brought in contact with the bony partition, between it and the root of the temporary tooth.

The manner of the destruction of the roots of the temporary teeth has been a subject of careful inquiry with the author for several years, and the more he has examined it, the more fully has he become convinced, that it is the result of the action of this fleshy tubercle. And while its formation seems to be the result of the contraction of the dental sac and its appendage, for the purpose of effecting the eruption of the tooth, it is especially charged with the removal of everything that would obstruct its passage.

In conclusion, it is only necessary to observe, that the temporary teeth are shed in the same order in which they first appear. After one pair has been shed, a sufficient time usually elapses before the shedding of another, for those of the same class of the permanent set to come forward and take their place. Thus, the jaws are never deprived, unless from some other cause than the destruction of the roots of the temporary, of more than two teeth in each jaw at any one time.

CHAPTER TENTH.

SECOND DENTITION.

THERE are no operations of the animal economy more singular or interesting than those exhibited in the gradual destruction of the roots of the temporary, and in the growth and eruption of the permanent teeth. The time of life when they occur, constitutes an important epoch in the history of every individual.

During childhood, the alveolar arches form only about the half of a circle, but by the gradual elongation of the jaws they ultimately, at adult age, form nearly the half of an ellipsis, so that the number of teeth required to fill them at the one period, is but little more than half the number required at the other.

Moreover, the food of children is principally vegetable, requiring but little mastication to prepare it for the stomach, whereas, that of adults, consists of an almost equal additional portion of animal, which, owing to the greater cohesion of its particles, require a more numerous and substantial set of instruments for its trituration.

So admirable is the economy of second dentition, that even before the shedding of the temporary teeth commences, and as soon as the jaws are sufficiently enlarged, four of the second set, one on each side, in each maxilla, make their appearance. Consequently, the number of teeth, after the completion of the first set, is never diminished, unless by accident or disease.

The rudiments of the permanent incisors and cuspidati have attained their full size at birth, and each is situated immediately behind its corresponding temporary tooth.

The permanent teeth, with the exception of the bicuspid, are considerably larger than the temporary, and during the time of their formation are situated in the segment of a much smaller circle. But before the shedding of the first begins, the latter, by an increase in the depth of the jaws, and the development of the alveolar processes, are brought forward, and at about the fifth year, they are situated immediately below in the lower and nearly above in the upper maxilla, occupying places in the alveolar border, corresponding in depth to the length of their respective roots.

By this arrangement the permanent teeth occupy the smallest possible space in the jaws. The central incisors and cuspidati nearly fill the anterior part of the arch, while the lateral are thrown back behind and partly between them.

The following concise description of the relative position of the teeth, at the fifth year after birth, is given by Mr. Bell. "In the upper jaw, the central incisors are situated, immediately beneath the nose, the lateral incisors thrown back behind the points of the cuspidati; and the base of the latter scarcely a quarter of an inch below the orbit. In the lower jaw, the cuspidati are placed at the very base of the bone, with only a thin layer beneath them, but the crowding is much less considerable than in the upper jaw, from the smaller comparative size of the incisors.

"The permanent central incisor of the lower jaw is placed immediately beneath the temporary, with its point directed a little backwards, behind the partially absorbed root of the latter. The lateral incisor, not yet so far advanced, is placed deeper in the jaw, and instead of being immediately beneath the temporary is situated with its point between the roots of this and the cuspidatus. The permanent cuspidatus is still very deeply imbedded in the bone, with its point resting between the roots of the temporary cuspidatus, and the first temporary molar. The two spreading roots of the latter encompass, as it were, within their span, the first bicuspid; and those of the sec-

ond temporary molar, in like manner, the second bicuspid. Nearly a similar arrangement is found to exist in the upper jaw, except that the teeth are altogether more crowded."

FIG. 51.

In Fig. 51 is exhibited a front and side view of the superior and inferior maxillary bones, with the temporary teeth *in situ*, the outer wall of the alveolar border being removed, shows the situation of the crowns of the permanent incisors, cuspidati, bicuspid and first molars.

The irritation consequent upon the eruption of the permanent teeth, is usually very slight, and with the exception of the *dentes sapientie*, seldom occasions much inconvenience. This is owing to the fact, that when second dentition commences, the system has acquired so much vigor and strength, as not to be easily affected by slight morbid impressions, and the gums offer, comparatively, little resistance to the eruption of the teeth of replacement, for when the temporaries drop out, the others are generally so far advanced as almost immediately to appear. Even when this is not the case, the cicatrix that forms over the permanent tooth is of so spongy a texture that it readily yields to the action of the absorbents. The process, too, is more gradual, from six to eight years being required for its completion, while the eruption of the teeth of first dentition is accomplished in less than half that time.

Second dentition usually commences at about six or seven years after birth, and is generally completed, as far back as

FIG. 51. A view of the superior and inferior maxillary bones of a child about four years old, with their exterior and outer walls removed, so as to show the crowns of the permanent teeth behind the roots of the temporary. The superior maxillary bones are separated at the median line, and about a quarter of an inch apart. Behind the second temporary, are seen the crowns of the first permanent teeth imbedded in the alveolar ridge.

the second molars, by the twelfth or fourteenth year. The *dentes sapientiae* seldom appear before the eighteenth or twentieth. The periods for the eruption of the adult teeth are, however, so variable, that it is impossible to state them with perfect accuracy. Sometimes the first permanent molars appear at four years, and the central incisors at five, at other times, these teeth do not appear before the ninth or tenth year.

But as it is of some importance that the periods of the eruption of the several classes of the permanent teeth should be known, we will state them with as much accuracy as possible.

First molars,	from	.	.	5 to 6 years.
Central incisors,	"	.	.	6 to 8 "
Lateral incisors,	"	.	.	7 to 9 "
First bicuspid,	"	.	.	9 to 10 "
Second bicuspid,	"	.	.	10 to 11½ "
Cuspidati,	"	.	.	11 to 12 "
Second molars,	"	.	.	12 to 14 "
Third molars, (<i>dentes sapientiae</i>),				17 to 21 "

But, as before stated, the periods for the eruption of the permanent teeth, like those of the temporary, are exceedingly variable. The cuspidati often appear before the second bicuspid, and in some cases, the *dentes sapientiae* not until the thirtieth or even fortieth year, and sometimes they never show themselves.

The author is acquainted with a gentleman who did not shed his left superior cuspidatus until he was twenty. A few months after, the permanent cuspidatus made its appearance. In fact, he has known the temporary cuspid in several instances to remain until the fortieth year, but when shed at this late age they are rarely replaced. In the *General Archives of Medicine* for June, 1840, the case of a woman is recorded, who, at the age of forty-three, erupted four permanent incisors, behind the temporary, which, up to this period, had not been shed. Four molars made their

appearance a year later, and M. Desirabode says he has met with similar cases.

Maury fixes the period for the eruption of the four first molars at from six to eight years, and Desirabode at from six to seven, but we have rarely known them to delay their appearance beyond the sixth year. Both of these authors, too, place the cuspidati, in the order of the eruption of the teeth, before the second bicuspid.

ACCRETION OF THE JAWS.

As the rudiments of the temporary teeth increase in size, a corresponding increase in the maxillary bones takes place, but during the earlier stages of the formation of the permanent teeth their growth is not so manifest. At about two and a half years after birth, they begin to elongate, and generally, at the fifth year, have acquired sufficient length to admit behind the second temporary, the first permanent molars. After the completion of first dentition, the part of the alveolar border occupied by this set of teeth, augment in dimensions but very little. The increase, after this time, is chiefly confined to the back part of the jaw, between the second temporary molars and the coronoid processes in the lower, and the maxillary tuberosities in the upper. The anterior part of the jaws do, however, augment a little, although so inconsiderable in extent, is the increase here, that some, and among whom are Hunter and Fox, have been induced to deny the fact. By the admeasurement of various jaws, at different ages, the writers just named have endeavored to prove, that the larger size of the permanent than the temporary incisors, is not greater than the larger dimensions of the temporary molars than the bicuspid, and that, consequently, no increase in this part of the jaw is necessary.

But a measurement of the same jaw, made after the first permanent molars have come through the gums, then again

after the eruption of all the teeth of replacement, will show that their measurements are not to be relied on.

M. Delabarre, in attempting to prove the incorrectness of these gentlemen's calculations, by a similar course of experiments, appears to have fallen into an opposite error, whence, it would seem, as is justly remarked by Mr. Bell, "That no comparison, instituted between the jaws of different individuals, can be relied on as conclusive." The only way by which we can arrive at the truth of the matter is by examining the same jaw at different ages, and comparing the several results. "This," says Mr. B., "I have repeatedly done, and have no hesitation in saying, that the ten anterior permanent teeth occupy a somewhat larger arch than the temporary ones which preceded them had done."

The transverse and perpendicular dimensions of the anterior part of the jaws continue to augment until the completion of second dentition.

In alluding to the influence which the pressure of the teeth has in determining an increase of the anterior part of the jaws, Delabarre contends, that while it is impossible for there to be any immediate pressure of these organs, except at the time when they are forcing their way through the enlarged alveolo-dental canals, their contact, at this period, gives rise to a mechanical increase; and he believes that previously to this period, the enlargement is carried on by the liquor contained in the dental sacs. He argues, therefore, that the jaws, besides the mode of accretion resulting from nutrition "have another, peculiar to themselves," coinciding with the development of the dental sacs, and the quantity of fluid which they contain, as also with the manner of the arrangement of the crowns of the permanent teeth between such as may be in the circle, whether belonging to first or second dentition.

That the dimensions of the alveolar arch may be increased by pressure upon the teeth from behind forwards, no one will deny, but to suppose the accretion of the jaws may be determined by the pressure of these organs against each

other, or by the fluid contained in the dental sacs, would be to suppose that the law that determines it in other bones, is inoperative here. In fact, to do this, would be attributing it rather to accident than to a natural operation of the economy.*

The elongation of the jaws produce a corresponding change in the form of the face. Thus, the face of a child is round, that of an adult is long and prominent.

The permanent incisors usually fill the space formerly occupied by the temporaries of the same class, and about one-half of that previously filled by the primitive cuspids. The other half of this space, together with a moiety of that before taken up by the first temporary molars, is occupied by the permanent cuspids.

The bicuspid occupy larger spaces, by one-fifth or sixth, than those occupied by the remaining moities of the first, and the whole of the second temporary molars.

Hence, it will be perceived, that the ten anterior permanent teeth occupy a somewhat larger space than that taken up by the temporary ones which preceded them, and that, were there no increase in the size of this portion of the arch, the regularity of their arrangement would be more or less disturbed. To prevent this a slight increase is necessary, but the dimensions of that portion of the alveolar border occupied by the temporary teeth is not materially increased until these teeth are shed, and then, as those of replacement come forward to take their place, they arrange themselves

* The formation of the alveolar processes, and that of the teeth, take place according to different laws. The jaws grow and enlarge in conformity with the general laws which preside over the increase of the osseous system. The alveolar arches, at birth, are little more than one inch in length; at nine years of age, they are nearly two inches, and at the period of perfect growth, at least two inches and a half long. The depth of the lower jaw in the fetus at the full time is the seventh, and in the adult the fifth of the whole height of the head. The teeth, on the contrary, uniformly appear with the breadth and thickness only, not the length, to which they will ever attain. In order that the development of these organs may take place in a regular manner, it is, therefore, necessary that a certain harmony be established between their sizes at different periods, and the alveolar edges of the jaws.—*Bourjery's Anatomy*.

in a somewhat larger arch. It is by this operation of the economy that the size of the alveolar border is augmented. In fact, a new alveolar ridge is formed, and this last is slightly larger than the first.

But there is not always an increase in the anterior part of the jaws ; on the contrary, the premature loss of one or more of the temporary teeth often occasions a contraction that frequently causes irregularity of the permanent set, and sometimes forces the first and second molars so far back, that the *dentes sapientiae* are thrown against the coronoid processes, and thus, in many instances, producing such severe inflammation in the muscles of this portion of the jaw, that the extraction of these latter teeth is rendered absolutely necessary.

About the third year, the jaws are more rapidly elongated, in order that the first permanent molars, which are at this time slowly advancing, may find room behind the second temporary molars. This elongation continues until the dental arches have become sufficiently enlarged for the reception of the whole of the permanent teeth.

It sometimes happens that the jaws in their accretion are badly developed, and have a faulty configuration. This may occur with one or both jaws. The alveolar arch is sometimes too narrow, having a compressed appearance, and projecting so far forward as to prevent the upper lip from covering the front teeth, thus imparting to the individual an exceedingly disagreeable appearance. In cases of this sort, the roof of the mouth, instead of having an oval arch, presents an irregular triangle. At other times the alveolar arch is too wide, so that the teeth are separated from each other, giving to the roof of the mouth a flattened aspect.

Similar defects are met with in the configuration of the lower jaw. Its sides may be too close together, causing the front teeth to project and to cross and strike on the outside of the upper incisors, or it may describe too large a circle.

These defects are regarded as hereditary, and are more

peculiar to some nations than others. The tendency to them is observable in early childhood, and even in infancy. Many suppose they are determined by a rickety diathesis of the general system, but this opinion has been proven to be incorrect by the fact, that those affected with this disease generally have good palates and well developed jaws. So far, indeed, from its having any agency in their production, rickets is thought by some to be produced by dentition, assigning as a reason for this belief, its frequent occurrence at the period of life, when this process is going on ; but this opinion is doubtless as incorrect as is the other and opposite one. These peculiarities in the formation of the jaws no doubt, often result as a consequence of the intermarriage of the people of one nation with those of another. The upper jaw will resemble in shape and size that of the father, and the lower that of the mother, or, vice versa.

There is a species of deformity in the upper jaw, the cause of which is equally difficult of explanation, characterized by one or more divisions of the upper lip, alveolar ridge and palatine arch, and necessarily accompanied by irregularity in the arrangement of the teeth. This deformity is always congenital, and often exceedingly difficult to remedy.

Any infringement of the laws of growth, or disturbance of the functional operations of any of the organs of the face or head, may, we have no doubt, determine an improper development of the jaws and a bad arrangement of the teeth ; on the other hand, a perfect, correct and healthful, performance of the several functions of all the parts concerned in the formation and growth of this portion of the organism, will secure a natural development and configuration of the maxillary bones.

CHAPTER ELEVENTH.

METHOD OF DIRECTING SECOND DENTITION.

THERE is nothing more destructive to the beauty, health and durability of the teeth, and no disturbance more easily prevented, than irregularity of their arrangement. In proportion, too, to the deviation of these organs from their proper position in the alveolar arch, are the features of the face and the expression of the countenance injured. It also increases the susceptibility of the gums and alveo-dental membranes to morbid impressions.

It is important, therefore, that the mouth during second dentition, should be properly cared for ; and so thoroughly convinced is the author of this, that he does not hesitate to say, that if timely precautions were used, there would not be one decayed tooth where there are now a dozen.

Much harm, it is true, may be done by improper meddling with the teeth during this period, but this so far from inducing a total neglect, should only make those having the care of children more careful to secure the services of scientific, accomplished practitioners.

For the judicious management of second dentition, much judgment and a correct knowledge of the normal periods of the eruption of the several classes of teeth, are required. All unnecessary interference with these organs, at this early period of life, should certainly be avoided, as it will only tend to mar the perfection at which nature ever aims. The legitimate duty of the physician being, as Mr. Bell correctly observes, "the regulation of the natural functions when deranged ;" he should never anticipate the removal by nature, of the temporary teeth, unless their extraction is called

for by some pressing emergency, such as a deviation of the permanent ones from their proper place, alveolar abscess, or exfoliation of the alveolar processes.

Among the few who have treated this subject in a full and philosophical manner, we will mention Delabarre, whose work contains the most explicit directions in regard to it of any that have as yet appeared. Owing to the superficial manner in which second dentition is frequently studied, this author was led to remark, "That the laws which govern the expansion, growth and arrangement of the teeth, are properly the patrimony of the physician, who should understand them, in order to direct the dentist, whenever (which unfortunately is very frequently the case) he is not furnished with sufficient information on all the duties of his profession." That this was necessary at the time Delabarre wrote, cannot be doubted; but at present we have many men in the dental profession better qualified to judge of what is required in cases of this sort than any general practitioner whose attention has never been specially directed to this peculiar department of practice.

The mouth should be frequently examined from the time the shedding of the deciduous teeth commences until the completion of second dentition; and when the growth of the permanent teeth so far outstrips the destruction of the roots of the temporary, that the former are caused to take an improper direction, such of the latter as have occasioned the obstruction, should be immediately removed. In the dentition of the upper front teeth, this should never be neglected; for, when they come out behind the temporaries, as they most frequently do, and are permitted to advance so far as to fall on the inside of the lower incisors, a permanent obstacle is offered to their subsequent proper adjustment.

When a wrong direction has been given to the growth of the lower front teeth, they are rarely prevented from acquiring their proper arrangement by an obstruction of this sort. They should not, however, on this account, be per-

mitted to occupy a wrong position too long, for the evil will be found easier of correction while recent, than after it has continued for a considerable length of time. The irregularity should be immediately removed.

The permanent central incisors of the upper jaw being larger than the temporaries of the same class, it might, therefore, be supposed, that the aperture formed by the removal of the one, would not be sufficient for the admission of the other, without an increase in the size of this part of the maxillary arch. It should be recollected, however, that by the time these teeth usually emerge from the gums, the crowns of the temporary lateral incisors are so much loosened by the partial destruction of their roots, as to yield sufficiently to the pressure of the former, to permit them to take their proper position within the dental circle. When this does not happen, the temporary laterals should be extracted.

Under similar circumstances, the same course should be pursued with the permanent lateral incisors and the temporary cuspids, and also with the permanent cuspids and the first bicuspid.

The bicuspid being situated between the fangs of the temporary molars, are seldom caused to take an improper direction in their growth. Nor are they often prevented from coming out in their proper place for want of room.

In the management of second dentition, much will depend on the experience and judgment of the practitioner. If he be properly informed upon the subject, and gives to it the necessary care and attention, the mouth will, in most instances, be furnished with a healthy, well arranged and beautiful set of teeth. At this time, "an opportunity," says Mr. Fox, "presents itself for effecting this desirable object," (the prevention of irregularity,) "but every thing depends upon a correct knowledge of the time when a tooth requires to be extracted, and also of the particular tooth, for often more injury is occasioned by the removal of a tooth too early than if it be left a little too long; because a new tooth, which has too much room long before it is required,

will sometimes take a direction more difficult to alter, than a slight irregularity occasioned by an obstruction of short duration."

Mr. Bell objects to the extraction of the temporary teeth, especially in the lower jaw, to make room for the permanent, on the ground that the practice is harsh and unnatural—that it often gives rise to a contraction of the maxillary arch, and that, in consequence of the peduncular connection that exists between the necks of the temporary teeth and the sacs of the permanent ones, it interferes with the uniform deposition of the enamel.

These objections, if they were well founded, should deter every dentist from adopting the practice, except as a dernier resort—as the least of two evils. But when the temporary teeth, by remaining too long, are likely to affect the arrangement, and, consequently, the health of the permanent teeth, they should be extracted; because, in that case, their presence is a greater evil than any that would be occasioned by their removal. This last objection is founded upon a false assumption, but on other grounds it may often be very properly urged. But as a general rule, they should be suffered to remain until their presence is likely to injure the permanent teeth and their contiguous parts.

When the permanent teeth are crowded, the lateral pressure is frequently so great as to fracture the enamel. If this cannot be prevented in any other way, one on each side should be extracted. It is better to sacrifice two than permanently to endanger the health of the whole.

M. Delabarre, in cases where the crowding is not very great, recommends passing a file between the teeth, as does also Mr. Bell, when only the space usually occupied by half of a tooth is required.

Notwithstanding the deservedly high authority of these two gentlemen, the author's experience compels him to condemn the practice. The apertures thus formed soon close, but not so perfectly as to prevent small particles of extraneous matter from lodging between the teeth, and being re-

tained there until they become putrid, vitiating the mucous and salivary secretions of the mouth, and thus causing the teeth to decay. In this manner, he has sometimes known the front teeth to be entirely destroyed ; and he has always observed, that teeth which had been thus filed, were invariably the first, and sometimes the only ones, to decay—thus clearly pointing out the pernicious tendency of the practice.

He does not, however, wish to be understood as conveying the idea that filing the teeth necessarily causes them to decay, for, when the file is used for any other purpose than to gain room, the apertures may be made large enough to prevent the approximation of the organs, and thus the bad effects resulting from the operation will be prevented.

The file should never be used, therefore, with a view to remedy irregularity ; the extraction of two teeth, one on each side of the jaw, however small the space required to be gained may be, is far preferable. The second bicuspid, *ceteris paribus*, should always be removed rather than the first, but sometimes the extraction of the first becomes necessary.

By the removal of two, ample room will be gained for the arrangement of all the remaining teeth, and the injury resulting from a crowded condition of the organs prevented.

On filing teeth, to prevent irregularity, Dr. Fitch judiciously remarks : “I consider the expediency of filing or not filing the teeth, ought to be a subject of serious deliberation on the part of the dental practitioner, and never, especially in young persons, perform the operation, unless obliged to do so, to cure actual disease.

“I was greatly surprised, in the late work of Mr. Bell, to see directions to file slightly irregular and crooked teeth, so as to gain about half a tooth of room.”

Nature, when permitted to proceed with her work without interruption, is able to perform her operations in a perfect and harmonious manner. But the functional operations of all the parts of the body are liable to be disturbed

from an almost innumerable number and variety of causes, and impairment of one organ often gives rise to derangement of the whole organism. For the relief of which, the interposition of art not unfrequently becomes necessary, and it is fortunate for the well being of man, that it can, in so many instances, be applied with success.

In sound and healthy constitutions, the services of the dentist are seldom required to assist or direct second dentition. In remarking upon this subject, Dr. Koecker observes, "that the children, for whom the assistance of the dentist is most frequently sought, are those who are either in a delicate, or at least in imperfect constitutional health; where the state of not only the temporary teeth, but of the permanent also, is to be considered; and, where both are found diseased, the future health and regularity of the latter require the greatest consideration of the surgeon.

"Irregularity of the teeth is one of their chief predisposing causes of disease, and never fails, even in the most healthy constitutions, to destroy, sooner or later, the strongest and best set of teeth, unless properly attended to. It is thus not only a most powerful cause of destruction to the health and beauty of the teeth, but also to the regularity and pleasing symmetry of the features of the face; always producing, though slowly and gradually, some irregularity, but not unfrequently the most surprising and disgusting appearance."

Finally, we would remark, that though nature is generally able to accomplish the task assigned her, yet there are times when she requires aid, and it is then, and then only, that the services of the dentist are needed. Therefore, whilst, on the one hand, we should guard against any uncalled for interference, we should, on the other, always be ready to give such assistance, as the nature of the disturbance presented to our notice, may require.

CHAPTER TWELFTH.

IRREGULARITY OF THE TEETH.

THE temporary teeth seldom deviate from their proper place in the alveolar arch, but with the permanent teeth, irregularity of arrangement is of frequent occurrence. The incisors and cuspids are more liable to take an improper position than any of the other teeth. The first and second molars seldom deviate from their proper place; for, like the teeth of first dentition, they rarely encounter obstruction in their growth and eruption.

The first molars being the first of the second set to appear, the ten replacing teeth are limited to that part of the arch occupied by the first set, and if this is too small, irregularity must of necessity ensue.

The *dentes sapientiae* are sometimes prevented from coming out in their proper place in the lower jaw, by want of room between the second molars and coronoid processes; and in the upper maxillary, by want of space between the last named teeth and the angle of the jaw.

When a *bicuspid* is forced from its proper place, it turns inwards towards the tongue, or outwards towards the cheek, according as it is in the upper or lower jaw. The cuspids, when prevented from coming out in their proper place, make their appearance either before or behind the other teeth. When they come out anteriorly, which they do more frequently than posteriorly, they often become a source of annoyance to the upper lip, excoriating the lining membrane, and sometimes causing ulceration.

The incisors of the upper jaw present a greater variety in the manner of their arrangement than any of the other teeth.

The centrals sometimes come out before and sometimes behind the arch; at other times, their sides, next the median line, are turned either directly or obliquely forwards towards the lip. The laterals sometimes appear half an inch behind the arch, looking towards the roof of the mouth; at other times, they come out in front of the arch, and at other times again, they are turned obliquely or transversely across it.

When any of the upper incisors are very much inclined towards the interior of the mouth, the lower teeth, at each occlusion of the jaws, shut before them, and become an obstacle to their adjustment. This is a very difficult kind of irregularity to remedy, often interfering with the lateral motions of the jaw.

The lower incisors sometimes shut in this manner even when there is no deviation of the upper teeth to the interior. In this case, the irregularity is owing to preternatural elongation of the lower jaw, which arises more frequently from some fault of dentition, than from any congenital defect in the jaw itself.

Sometimes, the superior maxillary arch is so much contracted, and the front teeth in consequence so much projected, that the upper lip is prevented from covering them. Cases of this kind, however, are rarely met with, but when they do occur, it occasions much deformity of the face, and forms a species of irregularity very difficult to correct.

From the same cause, the lateral incisors are sometimes forced from the arch, and appear behind the centrals and cuspids, the dental circle being filled with the other teeth.

There are many other deviations in the arrangement of these teeth. Mr. Fox mentions one that was caused by the presence of two supernumerary teeth of a conical form, situated partly behind and partly between the central incisors, which in consequence, were thrown forward, while the laterals were placed in a line with the supernumeraries; the central incisors, though half an inch apart, formed one row, and the laterals and supernumeraries, another. Mr.

F. says he has seen three cases of this kind. This description of irregularity is rarely met with.

M. Delabarre says, that cases of a transposition of the germs of the teeth occasionally occur, so that a lateral incisor takes the place of a central, and a central the place of the lateral. A similar transposition of a cuspidatus and lateral incisor is, also, sometimes seen. Two cases of this sort have fallen under the observation of the author.

The incisors of the lower jaw, being smaller than those of the upper, and in other respects less conspicuous, do not so plainly show an irregularity in their arrangement, nor is the appearance of an individual so much affected by it. Still it should be guarded against, for such deviation, whether in the upper or lower jaw, is productive of injury to the health of the teeth, and to the beauty of the mouth.

The growth of the inferior permanent incisors is sometimes more rapid than the destruction of the roots of the corresponding temporaries. In this case, the former emerge from the gums behind the latter, and sometimes so far back as greatly to annoy the tongue, and interfere with enunciation. At other times, the permanent centrals are prevented from assuming their proper place, because the space left for them by the temporaries is not sufficient for their reception. The irregularity in the former of these two cases, is greater than in the latter. The same causes, in like manner affect the laterals.

M. Delabarre mentions a defect in the natural conformation of the jaws, by which the upper temporary incisors on one side of the median line are thrown on the outside of the lower teeth, while the corresponding teeth, on the other side of the same line, fall within.* The same disposition, he

* Enfin il y a une espèce de torsion de l'une ou de l'autre mâchoire, et quelquefois de toute les deux, qui fait que les dents temporaires supérieures antérieures recouvrent les inférieures, d'après la meilleure disposition; tandis qu'à commencer de la ligne médiane, les semblables dents de l'autre côte, rentrent en dedans des inférieures; il est probable, dans ce cas, que si l'on n'y obvie, le même disposition se reproduira pour la seconde dentition.—*Traité de la Seconde Dentition*, p. 136.

says, may be expected, unless the defect is previously remedied, after the dentition of the permanent teeth. The author has never met with more than two cases of this sort, and he did not see the subjects of these until after they were adults.

TREATMENT.

In the treatment of irregularity, the means employed should accord with the indications of nature. When it is neither great nor complicated, and its causes are removed before the nineteenth or twentieth year, the teeth, without the aid of art, will in most cases, soon acquire their proper position.

When, however, the efforts of the economy are unavailing, recourse should be had to the dentist, who can, in most instances, bring the deviating organs to their proper position in the arch.

The practicability of altering the position of a tooth, after the completion of its growth, was well known to many of the early practitioners, but as before the commencement of the present century, the more particular object of the dentist, was, the insertion of artificial teeth, this branch of dentistry met with little attention. Fauchard and Bourdet were among the first to study orthodontia. They invented a variety of fixtures for adjusting such of the teeth as were not rightly arranged; but most of these were so awkward in their construction, and occasioned so much inconvenience to the patient, that they were seldom employed.

Mr. Fox was among the first to give explicit directions for remedying irregularity of the teeth, and his method of treatment has formed the basis of the established practice for more than fifty years. This long trial has proved it to be founded upon a knowledge of the laws of the economy, and much practical experience.

In describing the treatment of irregularity, we shall notice the means by which some of its principal varieties may

be remedied ; otherwise, the application of the principles of treatment would not be well understood, since it must be varied to suit each individual case.

As a general rule, the sooner irregularity in the arrangement of the teeth is remedied the better, for the longer a tooth is allowed to occupy a wrong position, the more difficult will be its adjustment. The position of a tooth may sometimes be altered, after the eighteenth, twentieth, or even the thirtieth year, but, it is better not to delay the application of the proper means until so late a period ; for a change of this kind may be much more easily effected before the several parts of the osseous system have acquired their full size, and while the process of new formation is in vigorous operation, than at a later period of life.

The age of the subject, therefore, should always govern the practitioner in forming an opinion as to the practicability of removing irregularity. Previously to the twentieth year, the worst varieties of irregularity may, in most cases, be successfully treated.

The first thing claiming attention in the treatment, is the removal of its causes. Whenever, therefore, the presence of any of the temporary teeth has given a false direction to one or more of the permanent, they should be extracted, and the deviating teeth pressed several times a day with the finger, in the direction they are to be moved. This, if the irregularity has been occasioned by the presence of a deciduous tooth, will, generally, be all that is required.

But, when it is the result of narrowness of the jaw, either natural or acquired, a permanent tooth on either side should be removed, to make room for such as are improperly situated. All the teeth being sound and well formed, the second bicuspid is the tooth which should be extracted, but if, as is often the case, the first permanent molars are so much decayed as to render their preservation impracticable, or, at least, doubtful, these teeth should be removed in their stead. After the removal of the second bicuspid, the first, usually, very soon fall back into the places

which they occupied, and furnish ample room for the cuspids and incisors. But if they fail to do this, they may be gradually forced back by inserting wedges of wood or gum elastic between them and the cuspids, or by means of a ligature of silk, or gum elastic, fastened to the first molar on each side, and securely tied. These should be renewed every day, until the desired result is produced.

The most frequent kind of irregularity, resulting from narrowness of the jaw, is the projection of the cuspids. These teeth, with the exception of the second and third molars, are the last of the teeth of second dentition to be erupted, and are, consequently, more liable to be forced out of the arch than any others, especially when it is so much contracted as to be almost entirely filled before they make their appearance. The common practice in such cases is to remove the projecting teeth. But as the cuspids contribute more than any of the other teeth, except the incisors, to the beauty of the mouth, and can, in almost every case, be brought to their proper place, the practice is injudicious. Instead of removing these, a bicuspid should be extracted from each side. When the space between the lateral incisor and first bicuspid is equal to one-half the width of the crown of the cuspid, the second bicuspid should be removed, but when it is less, the first should be taken out, for the reason, that, although the crown of the latter may be carried far enough back after the removal of the former, to admit the crown of the cuspid between it and the lateral incisor, the root of this tooth will remain in front and partly across the root of the first bicuspid, leaving a more or less prominent vertical ridge on the anterior part of the alveolar border, which, to some extent, at least, acts as an irritant to the gums and periosteum.

As the incisors of the upper jaw are more conspicuous than those of the lower, and when well arranged contribute more to the beauty of the mouth, their preservation and regularity are of greater relative importance. Hence, the removal of a lateral incisor, when it is situated behind the

circle of the other teeth, as is often done, with a view of remedying the deformity produced by false position, is a practice which cannot be too strongly deprecated, provided sufficient space can be made for it between the cuspid and central incisor, by the removal of a bicuspid from each side side of the jaw.

But, in describing the treatment of irregularity, we will commence with an incisor occupying an oblique or transverse position across the alveolar ridge, so that the cutting edge of the tooth, instead of being in a line with the arch, forms an angle with it from forty to ninety degrees. This variety of deviation is rarely met with in both centrals, but often occurs with one. Some dentists have recommended in cases of this sort, when the space between the adjoining central and lateral incisor is equal to the width of the deviating tooth, to turn the latter in its socket with a pair of forceps, or to extract and immediately replace it with the labial face of the organ outwards. It is scarcely necessary to say, that if a tooth is extracted or turned in its socket, the vessels and nerves from which it derives its nourishment and vitality are severed, and though its connection with the alveolus may be partially re-established, it will be liable to act as a morbid irritant.

The tooth, however, may be brought to its proper position without incurring the risk of injury by accurately fitting a gold ring or band with knobs on the labial and palatine sides; to each of these, a ligature should be attached.—Thus fastened to the ring, each end should be

FIG. 52.

carried back, one on either side, in front and behind the arch, and secured to the bicuspid in the manner as rep-

resented in Fig. 52, to act constantly upon the irregular tooth. The ligatures should be renewed from day to day, until the tooth assumes its proper position.

But before attempting to turn the deviating organ, it should be ascertained if the aperture between the adjoining teeth is sufficient to admit of the operation. If it is not, it should be increased by the extraction of a bicuspid from each side of the jaw, and moving the teeth in front of them backwards until sufficient room is obtained. The time required to do this will vary from three to eight or ten weeks, depending upon the number of teeth to be acted on, and the age of the patient.

Narrowness of the alveolar border is sometimes a cause of irregularity of the upper incisors. In this case, the centrals, usually project, though it sometimes happens that some are in front and some behind the arch, producing great deformity; to remedy which, the second bicuspid should be removed, unless the first molars are so much affected by caries as to render their preservation doubtful. In this case, they should be extracted, in place of the second bicuspid.

The following case will serve to illustrate the means employed for remedying this description of deformity. The subject was a young lady fifteen years of age. Her teeth presented the arrangement as seen in Fig. 53.

FIG. 53.

The second molars of the upper jaw occupied their proper position in the alveolar arch, or in other words, they were a little more than an inch and a quarter apart; the first molars were hardly an inch apart, and the first bicuspids were still nearer to each other. The cuspids, except having been pushed a little too far forward, occupied, very nearly, their proper position. The right central and left lateral incisors projected fully a quarter of an inch, lifting and otherwise annoying

and disfiguring the upper lip: the left central was thrown back and partly between the right central and left lateral, while the right lateral occupied a position in a line with it.

Without going into a minute detail of the method adopted for procuring the appliance employed, it will be sufficient to refer the reader to Fig. 54. This represents a plaster model of the teeth, alveolar border, palatine arch, and the apparatus employed for remedying the deformity. The second bicuspid were first extracted, then, by means of ligatures applied to the second molars and first bicuspid, and made fast to a band of gold passing on the outside of the arch, which were renewed every day, these teeth were brought out to their proper position in eleven weeks; this done, there was a space of nearly an eighth of an inch between the cuspids and first bicuspid; this was filled up, by bringing back with ligatures, the former to the latter. A ligature was next applied to the right lateral, passed through a hole in the gold band in front, and made fast. In ten days this tooth was brought to its proper place. A ligature was now attached to a knob soldered on the gold plate behind the teeth on the inner side of the alveolar border for the purpose, and tied tightly in front of the projecting right central incisor. In about three weeks this was brought to a position along side the lateral incisor of the same side. The left central was then, in like manner, brought forward, and the left lateral carried backward to its proper place.

After the deformity was corrected, the teeth presented the arrangement represented in Fig. 55, taken from

FIG. 54.

FIG. 55.

a plaster model of the upper jaw. To correct the irregularity in this case, required, in all, twenty-one weeks. If all the teeth could have been acted upon at the same time, the operation might have been accomplished in a shorter period. It was found necessary, too, in consequence of the diseased action occasioned by the apparatus, in the gums, to remove it every eight or ten days, and let it remain off each time twenty-four hours. It may be proper also, to observe, that every time the ligatures were removed, it was taken from the mouth, and the teeth thoroughly cleansed.

For moving a projecting incisor or cuspidatus backwards, a gold spiral spring was formerly employed. It was found to be more efficient than a ligature of silk, inasmuch as it kept up a constant traction upon the deviating tooth. But it is objectionable on account of the annoyance it causes the patient. A ligature of gum elastic is far preferable, and this material is now very generally employed in the treatment of every description of irregularity in which agencies of this sort are required.

There are other varieties of irregularity of the upper incisors, but we shall only notice one, which, from its peculiar character, is sometimes exceedingly difficult to remedy. It is, when one or more of these teeth are placed so far back in the jaw, that the under teeth come before it or them at each occlusion of the mouth.

FIG. 56.

Of this variety, Mr. Fox enumerates four kinds:—The first is, when one of the central incisors is situated so far back, that the lower teeth shut over it, while the other central re-

mains in its proper place, as represented in Fig. 56, copied from his work, as are also those which follow.

The second is, when both of the centrals have come out behind the circle of the other teeth, and the lateral occupy their own proper position, as represented in Fig. 57.

FIG. 57.

The third is, when the lateral incisors are thrown so far back, that the under teeth shut before them, while the centrals are well arranged, as exhibited in Fig. 58.

FIG. 58.

The fourth kind is, when all the incisors are placed so far behind the arch that the lower teeth shut before them, as in Fig. 59.

FIG. 59.

He might also have added to this variety a fifth description, for it sometimes happens that the cuspids of the upper jaw are thrown so far back, as to fall on the inside of the lower teeth. The author has met with several cases of this description of deviation.

Two things are necessary in the treatment of the kinds of irregularity just described; the first is, to prevent the upper and lower teeth from coming entirely together, by placing between them some hard substance, so that the former may not be prevented by the latter from being brought forward. The second is, the application of some fixture that will exert a constant and steady pressure upon the deviating teeth, until they pass those of the lower jaw.

For the accomplishment of this, various plans have been proposed. Duval recommends the application of a grooved or guttered plate, and Catalan has invented an instrument,

based, we believe, upon the same principle, but much better adapted to the purpose. We doubted the efficiency of the inclined plane of Catalan, until we had employed it, and found it an effectual and speedy method of moving deviating front teeth in the upper jaw, from behind the dental circle to their proper places. It acts with great force, and in precisely the proper manner for the accomplishment of the object.

FIG. 60.

FIG. 61.

The accompanying cuts, copied from Catalan, exhibit the manner in which his inclined plane is constructed. The one here represented, is applied to a case where all the upper incisors fall behind the lower front teeth. Its construction should be varied to suit the peculiarity of each case. If but one tooth deviates, only one inclined plane will be required. The apparatus should also be so adapted and secured to the teeth as to occasion as little inconvenience to

the patient as possible. The circular bar or plate of gold, running round in front of the teeth, should reach from the first molar on one side to the first molar on the other, and the plate, extending up from it should cover the grinding surfaces of these teeth, and be long enough to cover their lingual faces also, as the whole fixture will thereby be rendered firmer and more secure.

In the application of this principle for the correction of irregularity, the author has been in the habit of constructing the apparatus somewhat differently. With a brass model and zinc counter-model, he has a plate of gold struck

up over all the teeth, when practicable, as far back as the first or second molar, completely incasing them and the alveolar ridge in it. An encasement of this sort, possesses greater stability than can be obtained for an appliance like the one represented in Figs. 60 and 61.

FIG. 62.

FIG. 63.

FIG. 64.

In Fig. 62, is seen a representation of an inclined plane for bringing forward a central incisor which had come out about a quarter of an inch behind the circle of the other teeth. The manner of the action of this instrument upon the deviating tooth is shown in Fig. 63.

The plan proposed by Delabarre, is to pass silk ligatures round the teeth, in such a way that a properly directed and steady pressure will be exerted on such of the teeth as are situated behind the arch, and to keep the jaws from coming in contact, he recommends the application of a metallic grate, fitted to two of the inferior molars, (see Fig. 64,) taken from his treatise on second dentition. *a* Represents a ligature round the teeth, and *b* a metallic grate on two of the lower teeth.

This plan possesses the merit of simplicity, and occasions

but little or no inconvenience to the patient ; but it will sometimes be found not only inefficient, but also to loosen the teeth adjacent to those to be brought forward. The force on the irregular teeth, and those against which the ligatures act, being equal, and in opposite directions, the latter will be drawn back, while the former are brought forward ; and thus the means used for the correction of one evil, will sometimes occasion another. The author has used it, however, in some cases, with the most satisfactory results.

FIG. 65.

The means recommended by Mr. Fox, consists of a gold bar about the sixteenth part of an inch in width, and of proportionate thickness, bent to suit the curvature of the mouth, and fastened with lig-

atures to the temporary molars of each side. It is pierced opposite to each irregular tooth with two holes. The teeth of the upper and lower jaw are prevented from coming entirely together by means of thin blocks of ivory, attached to each end of the bar by small pieces of gold, and resting upon the grinding surfaces of the temporary molars. (See Fig. 65.)

FIG. 66.

After the instrument has been thus fastened to the teeth, silk ligatures are passed round such as have deviated to the interior, and through the holes opposite them, and then tied in a firm knot, on the outside of the bar. (See Fig. 66.)

The ligatures must be renewed every three or four days, until the teeth shall have come forward far enough to fall plumb on those that formerly shut before them and acquired

a sufficient degree of firmness to prevent them from returning to their former position. But as soon as the teeth shut perpendicularly upon each other, the blocks may be removed, and the bar alone retained.

Since 1830, many practitioners, both in England and the United States have substituted caps of gold for the blocks of ivory recommended by Mr. Fox; and instead of simply bending the bar, they now swage it between a metallic cast and die, so that all its parts, except those immediately opposite the irregular teeth, may be perfectly adapted to the dental circle. The apparatus, with these modifications, is more comfortable, and less liable to move upon the teeth.

Mr. Fox directs, that the blocks of ivory should be placed upon the temporary molars, but the caps of gold now substituted are entirely disconnected from the bar, and are often used after the moulting of these teeth; they are then placed upon the first permanent molars.

As the caps prevent the teeth from coming together, mastication, during the time they are worn, is, necessarily, performed on them. They should, therefore, be placed upon the largest and strongest teeth; and for this reason they should be applied to the molars.

The curved bar should be washed and the teeth cleansed every time the ligatures are renewed. If this be neglected, the particles of food that collect between it and the teeth, will soon become putrid and offensive, constituting a source of disease both to the gums and teeth.

But before the bar is applied, it should be ascertained whether there is sufficient space for the deviating teeth, and if there is not, room should be made in the manner as before described.

Some diversity of opinion exists as to the most suitable age for the correction of this description of irregularity. Mr. Fox, it would seem, preferred the period immediately previous to the moulting of the temporary molars—probably the tenth or eleventh year after birth.

Some think, that the forepart of the dental arch con-

tinues to expand until the second denture is completed, and that the bicuspid's afford a better support for the ends of the bar than any other teeth, and are content to wait until the fifteenth or even sixteenth year. But, though the arch does sometimes expand a little, yet even when the expansion occurs, it is generally so inconsiderable, that little advantage can be derived from it. Moreover, the arch, instead of expanding, is much more liable to contract whenever a vacancy occurs in the dental circle, either by the extraction or from the improper growth of one or more of the teeth; hence, the difficulty is apt to be increased by delay.

The evil, it is true, may be remedied at the fifteenth, seventeenth, or even eighteenth year; but it is rarely advisable to defer it to so late a period.

The most that is required in the treatment of irregularity of the lower incisors, is to remove a tooth, and to apply frequent pressure to the deviating organs. The lower incisors are less conspicuous than those of the upper jaw, and the loss of one, if the others are well arranged, is scarcely perceptible.

CHAPTER THIRTEENTH.

DEFORMITY FROM EXCESSIVE DEVELOPMENT OF THE TEETH AND ALVEOLAR RIDGE OF LOWER JAW.

FIG. 67.

WHEN the teeth of the lower jaw form a larger arch than those of the upper, the incisors and cuspids of the former shut in front of those of the latter, causing the chin to project, and otherwise impairing the symmetry of the face. This

description of deformity may result from two causes, namely, excessive development of the teeth and alveolar arch, and partial luxation and protrusion of the lower jaw. But we shall confine our remarks in this chapter to the treatment of that produced by the former.

TREATMENT.

The remedial indications of the deformity in question, consists in diminishing the size of the dental arch, which is always a tedious and difficult operation, requiring a vast amount of patience and perseverance on the part of the patient, and much mechanical ingenuity and skill on the part of the dentist. The appliances to be employed have, of necessity, to be more or less complicated, requiring the most perfect accuracy of adaptation and neatness of execution; they must also be worn for a long time, and, as a natural consequence, are a source of considerable annoyance.

In the treatment of a case of this sort, the first thing to

be done, is, to extract the first bicuspid on each side of the jaw. Sufficient room will be thus obtained for the contraction, which it will be necessary to effect in the dental arch, for the accomplishment of the object. An accurate impression of the teeth and alveolar ridge, should be taken, in the manner to be hereafter described, with wax, previously softened in warm water. From this impression, a plaster model is procured, and afterwards, a metallic model and counter-model.

FIG. 68.

This done, a gold plate of the ordinary thickness should be swaged to fit the first and second molars, if the second has made its appearance, and if not, the second bicuspid and first molar on each side of the jaw, so as completely to incase

these teeth. If these caps are not thick enough to prevent the front teeth from coming together, a piece of gold plate may be soldered on that part of each which covers the grinding surfaces of the teeth, and having proceeded thus far, a small gold knob is soldered on each side of each cap, and to each of which a ligature of silk or gum elastic is attached. These ligatures are now brought forward and tied tightly around the cuspids. When thus adjusted, the lower arch will present the appearance exhibited in Fig. 68. By this means the cuspids may, in fifteen or twenty days, be taken back to the bicuspids; but, if in their progress they are not carried towards the inner part of the alveolar ridge, the outer ligatures may be left off after a few days, and the inner ones only employed, to complete the remainder of the operation.

After the positions of the cuspids have been thus changed, the gold caps should be removed and a circular bar of gold, extending from one to the other, so constructed as to pass

about a quarter of an inch behind the incisors, should now be soldered at each end to the inner side of each cap, and a hole made through it behind each of the incisors, through which a ligature of silk may be passed, and after it is placed in the mouth, it is brought forward and tied tightly in front of each tooth. These ligatures should be renewed every day until the teeth are carried far enough back to strike on the inside of the corresponding teeth in the upper jaw.

Fig. 69 represents the appearance which a plaster model of the lower jaw presents with the last named apparatus on it, and an examination of this will convey a more correct idea of its construction, and the manner of its application, and mode of action than any description which can be given.

FIG. 69.

An appliance of this sort may be made to act with great efficiency in remedying the deformity in question, but, in its application, it is necessary that the caps be fitted with the greatest accuracy to the teeth, and they should be removed every day and thoroughly cleansed, as well as the teeth they cover. If this precaution is neglected, the secretions of the mouth, which collect between the gold caps and teeth, will soon become acrid and corrode the latter. It should always, therefore, be strictly observed.

CHAPTER FOURTEEN.

PROTRUSION OF THE LOWER JAW.

THIS deformity, although produced by a different cause from the one last described, is precisely similar to it, and gives to the lower part of the face an exceedingly morose and disagreeable appearance. It also interferes with mastication, and often with prehension and distinct utterance. It wholly changes the relationship which the teeth should sustain to each other when the mouth is closed. The cusps or protuberances of the bicuspid and molars of one jaw, instead of fitting into the depressions of the corresponding teeth of the other, often strike their most prominent points; at other times the outer protuberances of the lower molars and bicuspid, instead of fitting into the depressions of the same class of teeth in the upper jaw, shut on the outside of these teeth. The trituration of aliments is consequently rendered more or less imperfect.

The description of deformity under consideration is characterized by the protrusion of the lower jaw, and is supposed to be the result of a "natural partial luxation." It is of more frequent occurrence than the one which results from excessive development of the teeth and alveolar ridge, and requires, as before stated, an entirely different plan of treatment. It rarely occurs previously to second dentition, but is occasionally met with previously to that period.

TREATMENT.

The plan of treatment usually adopted, consists in fastening a small block of ivory on one of the lower molars, thick

enough to keep the front teeth about a quarter of an inch apart when the jaws are closed. Fox's bandage is now applied. This is buckled as tightly as the patient can bear with convenience, pressing the chin upwards and backwards. A piece of tough wood, slightly hollowed so as to fit the arch of the lower teeth, made narrow at the upper end, is introduced between the teeth several times a day, the concave portion resting upon the outside of the lower, and against the inside of the upper, employing at each time as much pressure as can be safely applied. By continuing this operation from day to day, for several weeks, the natural relationship of the jaws will, in most cases, be restored.*

The description of bandage here alluded to, and the manner of its application is represented in Fig. 70. When the protrusion of the lower jaw is accompanied by irregularity, means should, at the same time, be employed for remedying it. The earlier the treatment is instituted, the more easily will the deformity be overcome. It may, however, be successfully remedied at any time previously to the twentieth year of age, and sometimes at a much later period, but that after this time the operation becomes more difficult.

FIG. 70.

In cases where the lower front teeth shut over the upper, and thus cause a deformity of the face, it is important to discriminate correctly between those which result from malformation, and a protrusion of the jaw occasioned by partial

* An interesting article by Dr. J. S. Gunnell, on the treatment of deformities of this kind, is contained in one of the early volumes of the American Journal of Dental Science.

luxation, as the remedial indications in the two are entirely different. Those which would prove successful in the one, would prove unsuccessful in the other. But, fortunately, deformity arising from the last mentioned cause, is, comparatively, of rare occurrence; hence the dentist is seldom called upon to exercise his ingenuity and skill in its treatment.

CHAPTER FIFTEENTH.

PECULIARITIES IN THE FORMATION AND GROWTH OF THE TEETH.

IN the development and growth of the various parts of the body, curious and interesting anomalies are sometimes observed, but in no portion of it are they more frequent in their occurrence or diversified in their character than in the teeth. But aberrations in the formation and growth of these organs, are, for the most part, confined to the teeth of second dentition.

Mr. Fox gives a drawing of a tooth very nearly resembling the letter S. The malformation was caused by an obstructing temporary tooth. The author has also met with several examples of teeth similarly deformed, and from like causes.

The molars of the upper jaw sometimes have four and even five roots, and those of the lower, three and occasionally four. The crowns of the teeth, also, frequently present deviations from the natural shape equally striking and remarkable.

The next peculiarity to be noticed, is that of size, and in this respect the teeth are very variable. Even in the same mouth, the want of relative proportion between the different classes of teeth, is sometimes quite conspicuous. But examples of this kind are not very frequent, for where there is an increase or diminution in the size of the teeth of one class, there is generally a corresponding increase in those of the other.

Aberrations of this character are probably dependent upon some diathesis of the general system, whereby the teeth,

during the earlier stages of their formation, are supplied with an excessive or diminished quantity or nutriment.

Some very remarkable deviations have been known to take place in the growth of the teeth. The most singular case on record, is that narrated by Albinus: "Two teeth," says he, "between the nose and the orbits of the eye, one on the right side and the other on the left, were enclosed in the roots of those processes that extend from the maxillary bones to the eminences of the nose. They were large, remarkably thick, and so very like the canini, that they might have seemed to be these teeth themselves, which had not before appeared; but the canines themselves were also present, more than usually small and short, and placed in their proper sockets. The former, therefore, appear to have been the new canini, which had not penetrated their sockets, because they were situated where these same teeth are usually observed to be in children. But what is still more remarkable, their points were directed towards the eyes, as if they were the new eye teeth inverted. And they were also so formed, that they were, contrary to what usually happens, convex on the posterior, and concave on the anterior."* A case of a somewhat similar character is mentioned by Mr. John Hunter.

The following case is in the words of Mr. G. Wait: "While I was prosecuting my anatomical studies, I was struck with the appearance of a cuspidatus of the upper jaw; it was short and appeared as if the body of the tooth was in the jaw, and that it was the tip of the root that presented itself. Upon further examination, I found this verified; and

* "Dentes duo inter nasum et orbes oculorum, dexter sinisterque, inclusi in radicibus processum quibus ossa maxillaria ad eminentem nasum pertinent. Longi sunt, crassitudinis insignis. Similes maximi caninis, ut videri possint illi ipsi esse, non nati. At aderant præterea canini præter consuetudinem parvi, et brevis, suis infixi alveolis. Itaque videantur esse canini novi, qui non eruperint uptote ibi loci collocati, ubi sunt novi illi in infantibus. Sed quod miremur sursum divecti, tanquam si sint canini novi inversi. Et it quoque formati sunt ut, contra quamalii, a posteriore parte gibbi, ab anteriore sinuati sint," &c.—*Academ. Anastat.* liber 1, p. 54.

after the cranium and lower jaw were properly macerated and cleansed, I found one of the lower bicuspid in the same manner."

The author can readily imagine that a cuspidatus of the upper jaw might, while in a rudimentary state, by some false or unnatural attachment of the dental sac, be so altered in its position, as to pass up, in its growth, between the nose and orbit. But that the crown, after having been thus turned round in the socket, should remain stationary, while the fang passed down and appeared outside of the gum, is a most extraordinary and remarkable anomalism. In the former instance, the tooth might still continue to derive the nutriment necessary for its vitality from the dental vessels; but in the latter case, it could not, because the apex of the root, the place where the vessels and nerves enter, were entirely outside of the gum. He cannot, therefore, but think that the crown, divested of enamel, was mistaken for the root.

The following is one of the several cases of deviation in the growth of the teeth, that have come under the author's observation. In 1840, he was requested to extract a tooth for a lady of Baltimore, under the following circumstances: she had, for a time, experienced a great deal of pain in her upper jaw, and supposed it to originate from the second molar of the right side, but which was perfectly sound. Meanwhile her general health became impaired, and her attending physician, thinking that the local irritation might have contributed to her debility, advised her to have the tooth removed. On extracting it, the cause of the pain at once became apparent. The *dens sapientiæ*, which had not hitherto appeared, was discovered with its fangs extending back to the utmost verge of the angle of the jaw; while its grinding surface had been in contact with the posterior surface of the crown and neck of the tooth just extracted. On the removal of the wisdom tooth, the pain ceased.

About the middle of December, 1849, a youth aged sixteen, applied to the author to extract a right superior bicus-

pid, which, he said, was ulcerated at the root. On examining his mouth, he discovered but one bicuspid, but above and between the root of this and that of the first molar, he observed a small fistulous opening. On introducing a small probe, it immediately came in contact with the crown of a tooth looking towards the malar process of the superior maxillary, which, on extraction, proved to be the second bicuspid.

The author has in his possession several molar and bicuspid teeth, which have small nodes upon their necks, covered with enamel; and there is a jaw in the Museum of the Baltimore Dental College, which has five teeth presenting this anomaly.

The author has two teeth in his possession, presented to him by his brother, the late Dr. John Harris, of most singular shape. They were extracted in July, 1822, from the right side of the upper jaw of a young gentleman, nineteen years of age, by the name of Crawford. They occupied the place of the first and second bicuspids, and their crowns are almost wholly imbedded in lamellated dentine, that should have constituted their roots, but which are entirely wanting. Judging from their appearance, one would be inclined to suppose, that their sacs failing to contract, they remained stationary in their sockets, and as the base of the pulps elongated, they came in contact with the bottom of the alveoli and were caused to bulge out and to be reflected upon their crowns—to the enamel of which, nearly to their grinding surfaces, they are perfectly united. For some time previously to the extraction of these teeth, they had been productive of considerable irritation and pain in the gums and jaw, and it was for the relief of this, that they were removed.

Since the publication of the second edition of this work, the author has seen a still more remarkable deviation in the growth of a tooth. It is in the upper jaw of an adult skull in the Museum of the Baltimore Dental College. The natural teeth are all well formed, and regularly arranged

in the alveolar border, but between the extremities of the roots of the superior central incisors, in the substance of the jaw, there is a supernumerary tooth, the crown of which looks upwards towards the crest of the nasal plates of the two bones. The whole tooth is about one inch in length, and the apex of the crown is nearly on a level with the floor of the nasal cavities. There is also in the museum of this institution a central incisor of the upper jaw, with the root bent upon, and in contact with, the labial surface of the crown.*

* This tooth was presented to the author, by Dr. Williams, dentist, of Alexandria, Va.

CHAPTER SIXTEENTH.

OSSEOUS UNION OF THE TEETH.

INCLOSED as each tooth is, in a distinct sac, and separated on either side by a bony partition, from the adjoining teeth, until after the completion of the formation of the enamel, it is difficult to conceive how osseous union could take place between two of these organs, and, we confess, that until we actually witnessed an example of it, which we did for the first time in 1836, we were inclined to doubt the possibility of such an occurrence.

During a visit to the city of Richmond, Va., in April, of the above mentioned year, we had an opportunity of seeing two cases. One consisted in the union of the crowns of the central incisors of the upper jaw, the palatine surface of which presented the appearance of one broad tooth, while anteriorly, they had the semblance of two teeth; the other case, consisted in the union of the right central and lateral incisors of the lower jaw.

A professional friend of Virginia, informed the author, in a conversation some years since, that he had met with a case of osseous union between a second bicuspid and first molar of the lower jaw, which was so palpable, that there could have been no doubt of its existence.

Mr. Fox has given the drawings of four cases, the originals of which, as Mr. Bell tells us, are still to be seen in the museum of Guy's Hospital. Mr. B. also informs us, that he has seen four other examples.

Dr. Koecker is sceptical with regard to the existence of osseous union of the teeth, and attributes to those who assert that they have met with cases of it, "a weak credu-

lity—a love of the marvellous—or a desire to impose upon the world.”

Cases of this sort, it is true, are of rare occurrence, and a connection of the fangs of two teeth, by an intervening portion of the alveolus, is very easily mistaken for osseous union of the roots themselves. A few years since, in extracting a second molar of the upper jaw, the author brought the dens sapientiæ along with it. At first he thought there was osseous union of the roots, but upon close examination, found a very thin portion of the alveolar wall between, to which their roots were firmly attached. Such a case as this, would, in many instances, be set down as an example of osseous union.

It is easy to account for a *lusus naturee* of this kind, by supposing a previous union of the pulps of the two teeth. But from the order in which the teeth are erupted, some classes appearing long before others, it would, on this supposition, seem that it could only occur between the central incisors. It is not, however thus limited. The central and lateral incisors, the bicuspid, and the molars, are sometimes united.

An osseous union of the teeth, is, fortunately, of rare occurrence; if it were otherwise, it would be productive of many accidents in the extraction of teeth. Apart from this consideration, it can be of but little importance, either to the practitioner, or to the physiologist.

Since the publication of the first edition of this work, several cases of osseous union of the teeth have fallen under the observation of the author, and he now has several specimens in his anatomical collection. He has five examples of osseous union of the temporary teeth.*

The author has more recently met with several other examples of osseous union of temporary teeth.

* For the specimens above alluded to, the author is indebted to Dr. Cassell, Mr. Townsend and Dr. Dwinelle.

CHAPTER SEVENTEENTH.

SUPERNUMERARY TEETH.

THE development of supernumerary teeth is usually confined to the anterior part of the mouth, and more frequently to the upper than to the lower jaw. They sometimes, however, appear as far back as the *dentés sapientiæ*, and Hudson says, he has seen them behind these teeth. We have now in our anatomical collection, two supernumerary teeth that were extracted, one from behind, and the other at the side, of one of the upper wisdom teeth.*

The crowns of supernumerary teeth which appear in the anterior part of the mouth, are usually of a conical shape, and for the most part, situated between the central incisors; they usually have short, knotty roots; sometimes, however, they bear so strong a resemblance to the other teeth, that it is difficult to distinguish the one from the other. We once saw too lateral incisors in the lower jaw, both of which were so well arranged, and perfectly formed, that it was impossible to determine which of the two ought to be considered as the supernumerary. Mr. Bell mentions a case, in which there were five lower incisors, all of which were well formed and regularly arranged. The author has met with several examples in which supernumerary teeth in the lower jaw so closely resembled the natural incisors, that no difference could be discerned between them. He has also seen examples of three lateral incisors in the upper jaw, where it was impossible to determine which was the supernumerary.

* These teeth were removed by Dr. Chewning, dentist, of Fredericksburg, Va.

Supernumerary cuspids rarely if ever occur, but supernumerary bicuspidis are occasionally met with. Delabarre says, he has seen them ; and we have met with three examples of the sort ; in each of these instances the teeth were very small, not being more than one-fourth as large as the natural bicuspidis, with oval crowns, and placed partly on the outside of the circle, and partly between the bicuspidis. We extracted one of them, and have it still in our possession. Its root is short, round, and nearly as thick at its extremity as it is at the neck of the tooth.

The supernumerary teeth that appear further back than the bicuspidis, though much smaller, bear a strong resemblance to the *dentes sapientiae*.

Supernumerary teeth, although generally imperfect in their formation, are less liable than other teeth to decay. This may be attributable to the fact, that they possess a lower degree of vitality, are harder, and, consequently, not so susceptible to the action of the causes that produce the disease.

Although the occurrence of supernumerary teeth rarely disturbs the arrangement of the others, their presence is sometimes productive of the worst kind of irregularity ; and even when they do not have this effect, they impair the beauty of the mouth, and, for this reason, should be extracted as soon as their crowns have completely emerged from the gums.

To the practitioner of dental surgery, the occurrence of supernumerary teeth is interesting, only in so far as it affects the beauty of the mouth and the relationship which the teeth of the upper jaw sustain to those of the lower ; but to the physiologist, it involves the question, what determines their development ? But in propounding this interrogatory it is not our intention to enter upon its discussion in this place, as it forms no part of the design of the present treatise.

CHAPTER EIGHTEENTH.

THIRD DENTITION.

THAT nature sometimes makes an effort to produce a third set of teeth, is a fact which, however much it may be disputed, is now so well established, that no room is left for cavil or doubt.

The following interesting particulars are taken from *Good's Study of Medicine*.

“We sometimes, though rarely, meet with playful attempts on the part of nature, to reproduce teeth at a very late period of life, and after the permanent teeth have been lost by accident, or by natural decay.

“This most commonly takes place between the sixty-third and eighty-first year, or the interval which fills up the two grand climacteric years of the Greek physiologist ; at which period the constitution appears occasionally to make an effort to repair other defects than lost teeth. * * *

“For the most part, the teeth, in this case, shoot forth irregularly, few in number, and without proper fangs ; and, even where fangs are produced without a renewal of sockets. Hence, they are often loose, and frequently more injurious than useful, by interfering with the uniform line of indurated and callous gums, which, for many years perhaps, had been employed as a substitute for the teeth. A case of this kind is related by Dr. Bisset, of Knayton, in which the patient, a female in her ninety-eighth year, cut twelve molar teeth, mostly in the lower jaw, four of which were thrown out soon afterwards, while the rest, at the time of examination, were found more or less loose.

“In one instance, though never more than one, Mr. Hun-

ter witnessed the reproduction of a complete set in both jaws apparently with a renewal of their sockets. 'From which circumstance,' says he, 'and another that sometimes happens to women at this age, it would appear that there is some effort in nature to renew the body at that time.'

"The author of this work once attended a lady in the country, who cut several straggling teeth at the age of seventy-four; and, at the same time, recovered such an acuteness of vision, as to throw away her spectacles, which she had made use of for more than twenty years, and to be able to read with ease the smallest print of the newspapers. In another case, that occurred to him, a lady of seventy-six, mother to the late Henry Hughes Eryn, printer of the journals of the House of Commons, cut two molars, and at the same time completely recovered her hearing, after having for some years been so deaf as to be obliged to feel the clapper of a small hand-bell, which was always kept by her, in order to determine whether it rung or not.

"The German Ephemerides contain numerous examples of the same kind; in some of which, teeth were produced at the advanced age of ninety, a hundred, and even a hundred and twenty years. One of the most singular instances on record, is that given by Dr. Slade, which occurred to his father; who, at the age of seventy-five, reproduced an incisor, lost twenty-five years before, so that, at eighty, he had hereby a perfect row of teeth in both jaws. At eighty-two, they all dropped out successively; two years afterwards, they were all successively renewed, so that at eighty-five, he had at once an entire set. His hair, at the same time, changed from a white to a dark hue; and his constitution seemed, in some degree, more healthy and vigorous. He died suddenly, at the age of ninety or a hundred.

"Sometimes these teeth are produced with wonderful rapidity; but in such cases, with very great pain, from the callosity of the gums, through which they have to force themselves. The Edinburg Medical Commentaries supply us with an instance of this kind. The individual was in

his sixty-first year, and altogether toothless. At this time, his gums and jaw-bones became painful, and the pain was at length excruciating. But, within the space of twenty-one days from its commencement, both jaws were furnished with a new set of teeth, complete in number."

A late physician of Baltimore informed the author in 1838, that an example of third dentition had come under his own observation. The subject a female, at the age of sixty, he assured him, erupted an entire set in each jaw.

The following extract of a letter from a professional friend,* describes another very interesting case.

"I have just seen a case of third dentition. The subject of this 'playful freak of nature,' as Dr. Good styles it, is a gentleman residing in the neighborhood of Coleman's Mill, Caroline county, Virginia. He is now in his seventy-eighth year, and, as he playfully remarked, 'is just cutting his teeth.' There are eleven out, five in the upper, and six in the lower jaw. Those in the upper jaw, are two central incisors, one lateral and two bicuspid, on the right side. Those in the lower, are the four incisors, one cuspidatus and one molar. Their appearance is that of bone, extremely rough, without any coating or enamel, and of a dingy brown color."

Two cases somewhat like the foregoing, have come under the author's observation. The subject of the first was a shoemaker, Mr. M., of Baltimore, who erupted a lateral incisor and cuspidatus at the age of thirty. Two years before this time, he had been badly salivated, and, in consequence, lost four upper incisors, and one cuspid. The alveoli of these teeth exfoliated, and, at the time he first saw him, were entirely detached from the jaw and barely retained in the mouth by their adhesion to the gums. On removing them, he found two white bony protuberances, which, on examination, proved to be the crowns of an incisor and cuspidatus. They were perfectly formed, and though much

* Dr. J. D. McCabe.

shorter than the other teeth, yet, up to the present time, 1845, have remained quite firm in the jaw.

The subject of the other case, was a lady, residing near Fredericksburg, Virginia, who erupted four right central incisors of the upper jaw successively. One of her temporary teeth, in the first instance, had been permitted to remain too long in the mouth, and a permanent central incisor, in consequence, came out in front of the dental arch. To remedy this deformity, the deciduous incisor was, after some delay, removed; and, about two years after, the permanent tooth, not having fallen back into its proper place, was also extracted. Another two years having elapsed, another tooth came out in the same place, and in the same manner; and, for similar reasons, was also removed. To the astonishment of the lady and her friends, a fourth incisor made its appearance in the same place, two years and a half after the extraction of the first permanent tooth. When it had been out about eighteen months, the author was called in by the lady, who wished him, if possible, to adjust it. Finding that it could not be brought within the dental circle, he advised her to have it extracted, and an artificial tooth placed in the proper place in the arch.

In the second number of the eighth volume of the *American Journal of Dental Science*, the history of a case of four successive dentitions of the upper central incisors is given.*

It is said that the efforts made by nature, for the production of a third complete set of teeth, are so great, that they exhaust the remaining energies of the system; and as a consequence, that occurrences of this kind are generally soon followed by death.

The author is not aware that any attempt has ever been made to explain the manner of the origin and formation of the teeth of third dentition. The rudiments of the teeth of first and second dentition originate from mucous membrane,

* Dr. W. H. Dwinelle.

while those of third dentition would seem to be the product of the periosteal tissue or bone.

In obedience to what law of developmental anatomy are the teeth of third dentition formed? Certainly not to any one primitively impressed upon the animal economy, as they have never been known to appear while the teeth of second dentition remain in the jaws. If the establishment of the law which governs the development of a part, depends upon a certain condition of other contiguous parts, it is possible that the following may be a correct explanation of the phenomenon of third dentition. Certain parts, in certain states or conditions, and in particular locations, perform functions peculiar to themselves. In other words, the condition and location of a part determines the function or functions it performs. For example, when the mucous membrane along the course of the alveolar border begins to assume a duplicated or grooved condition, which it does at about the sixth week of intra-uterine existence, dental papillæ shoot up from it, and when, by a similar duplication of this same tissue, behind the sacs of the temporary teeth, forming what Mr. Goodsir styles "cavities of reserve," the papillæ of the permanent teeth, one from the bottom or distal extremity of each duplication, begins to be developed. Hence, it would seem that this particular state or condition of this tissue, and in these particular locations is necessary to determine the development of teeth germs. This arrangement or condition of mucous membrane, in these particular locations, which always result from the development of the fetus, may be sometimes produced by accidental causes, after all the organs of the body have attained their full size, or at any time during life; and when it does occur, it is not unreasonable to suppose that a new tooth papilla should be formed. Proceeding still farther, the development of a dental papilla is the signal for the production of a dental follicle, which ultimately becomes a sac, and then an organ to supply the tooth, now considerably advanced in the process of formation, with a covering of enamel. But

as the maxillary bone has previously attained its full size, it rarely, if ever, happens that alveoli are formed for these accidental productions, and, consequently, they seldom have roots, or if they do, they are very short and blunt. They are usually connected to the periosteum of the alveolar border, and this union is sometimes so close and intimate, that very considerable force is necessary for their removal, or at least, so far as our own observations go upon the subject, and we have had occasion to extract several in the course of our practice. As a general rule, however, they loosen in the course of a few years and drop out.

But it may be asked, how are such accidental duplications of the mucous membrane formed? This is a question, we admit, which it may not be easy to answer satisfactorily, but we do not think it at all improbable, that they sometimes occur during the curative process that follows the removal of one or more teeth. The granulated walls of the gums surrounding an alveolus from which a tooth has been extracted, may become covered with this tissue before the socket is filled with a deposit of new bone, or, at any rate, of the surfaces of the duplicated membrane near the bone, and whenever such arrangement or condition of this tissue takes place, upon the alveolar border, and that it may, occasionally, we think there can be no question, it is probable that a new tooth papilla is produced, which, in the progress of its development, induces the formation of the various appendages necessary to the production of a perfect tooth.

This, in the opinion of the author, is the only way that these fortuitous productions can be accounted for in accordance with true physiological principles. It seems impossible to explain the manner of their formation in any other way. All must admit that the presence of mucous membrane is necessary, and we cannot conceive of any other way by which its presence beneath the general surface of the gums can be accounted for; but if we admit this explanation to be correct, the question is at once solved. We believe it is also owing to

the accidental occurrence of a certain arrangement or condition of the mucous membrane concerned in the production of the permanent teeth, consisting, most likely, of the formation of one or more "cavities of reserve" than is called for by the teeth of this dentition, that the development of supernumerary teeth are attributable.

The operations of nature, it is true, are so secretly carried on, that we cannot see the precise *modus operandi* by which they are effected, yet in the development of the various organs and structures of the body, we may see them at the various stages of their growth, as well as what precedes their arrival at these various stages in the progress of their formation, and upon which their accretion would seem to be dependent. The periods for the arrival of these stages of development, though somewhat irregular, occur for the most part, in normal conditions of the body, at certain fixed epochs. Thus, the papilla of the first temporary molar may usually be seen between the sixth and seventh weeks of intra-uterine existence, but previously to this time a slight groove or depression is observable in the mucous membrane of the part from whence it has its origin. The same is true with regard to the papillæ of all the other teeth, though the time for the commencement of their formation occurs at later periods. The peculiar change which takes place in the arrangement of the mucous tissue here, as well as the periods at which they occur, is doubtless determined by certain stages in the development of other parts, and these very likely, may determine the established number which the teeth of both dentitions have.

If the foregoing views which we have advanced be correct, these fortuitous productions are not the result of a mere freak of nature, as they are sometimes facetiously styled. They are the result of the operation of an established law of the economy; and although, after the completion of the teeth of second dentition, its course is suspended, the occurrence of a similar arrangement or condition of the mucous tissue in the parts in question, will again put it in operation.

PART SECOND.

CHAPTER FIRST.

GENERAL CONSIDERATIONS.

THE susceptibility of the human body to morbid impressions differs in different individuals. In some, its functional operations are liable to be deranged from the most trifling causes; in others, they are less easily disturbed. Nor do the same causes always produce the same results. Their effects are determined by the tendency of the organism and the susceptibility of the part on which they act; and this is true, both with regard to constitutional and local diseases: with the organism generally and all its parts separately considered, but with none more than the teeth, gums and alveolar processes. The teeth of some persons are so susceptible to the action of corrosive agents, as to become involved in general and rapid decay, as soon as they emerge from the gums; while those of others, though exposed to the same causes, remain unaffected through life. A similar difference of susceptibility also exists in the parts within which these organs are contained.

With the teeth, these differences of susceptibility to morbid impressions, are implanted in them at the time of their formation, and are the result of the different degrees of perfection in which this process is accomplished. In proportion as these organs are perfect, is their capability of resisting the action of destructive agents increased, and as they are

otherwise, it is diminished. This is true of every part of the body; but as the teeth are formed, so they continue through life, if not impaired by disease, except that they gradually acquire a very slight increase of density, whereby their liability to caries is correspondingly lessened.

Not so, however, with the other parts of the body. They may be innately delicate, or imperfectly developed, and afterwards become firm and strong, or be at first healthy and well formed, and subsequently become impaired; and in proportion as they undergo these changes, is their susceptibility of disease, increased or diminished. But the teeth are not governed by the same laws, neither physical nor vital, that regulate the operations of the other parts of the animal economy. Not only is the manner of their formation, but their diseases, also, are different. The other tissues of the body, not excepting the osseous, are endowed with recuperative powers, whereby an injury is repaired by their own inherent energies, but the teeth do not possess such attributes.

Assuming these propositions to be true, and that they are, especially those with regard to the teeth, as we shall endeavor to show, it becomes an object of considerable importance to discover the signs by which the susceptibility of the human organism to disease, may be determined. But to do this, except in so far as the teeth, gums and alveolar processes are concerned, is not our present object, yet, in the prosecution of the task we have undertaken, we may have occasion to advert to certain constitutional and local tendencies, indicated by the appearance and condition of the teeth and other parts of the mouth.

M. DELABARRE affirms, that by an inspection of the teeth, we can ascertain whether the innate constitution is good or bad, and our own observations go to confirm the truth of this opinion; but as this author adds, these are not the only organs that should be interrogated. The lips, the gums, the tongue, and the fluids of the mouth should also be examined to discover the health of the organism, and ascertain wheth-

er the original condition of the constitution has undergone any change.

Those who have not been in the constant habit of closely observing the appearances met with in the mouth, may be sceptical with regard to the information that may thus be derived, but those who have studied them with care, will not hesitate to say, that they are, in many instances, more certain and accurate than any which can be obtained from other physical appearances. For example—the periods of the dentinification of the different classes of both sets of teeth being known, we are enabled to say whether the innate constitution is good or bad by the physical condition of these organs, for as the functions of the organism are at this time healthily or unhealthily performed, will they be perfect or imperfect; or in other words, will their texture be hard or soft.

It is well known to writers on odontology, that the teeth of the child, like other parts of the body, usually resemble those of its parents, so that when those of the father or mother are bad or irregularly arranged, a similar imperfection is generally found to exist in those of the offspring, but this does not necessarily follow, and when it does, it is the result of the transmission of some constitutional impairment, whereby the formative operation of these organs is either disturbed or prevented from being effected in a perfect and healthy manner. The teeth of the child, therefore, may be said to depend on the health of the mother, and the aliment from which it derives its subsistence. If the mother is healthy, and the nourishment of the child be of good quality, the teeth will be dense and compact in their texture, generally well formed and well arranged, and as a consequence less liable to be acted on by morbid secretions, than those of children deriving their being from unhealthy mothers, and subsisting upon aliment of a bad quality. Temperament, also, exercises an influence upon the functional operations of the body. Upon it the constitutional health depends to a greater extent than pathologists gener-

ally admit, and hence it is, that that of the child usually partakes of that of one or other, or both, of its parents. "This," says M. Delabarre, "is particularly observable in subjects that have been suckled by a mother or nurse whose temperament was similar to theirs." To obviate the entailment of this evil, he recommends mothers, having teeth constitutionally bad, to abstain from suckling, and that this highly important office be entrusted to a nurse having good teeth—asserting at the same time, that by this means, the transmission of so troublesome a heritage as bad teeth, may be avoided.

Depending, then, as the physical condition of the teeth, and the organism generally, confessedly do, upon the quality of the nourishment from which subsistence is derived during infancy and childhood, it is highly essential that this be good, and that that, especially, derived from the breast, be from those only who are in the enjoyment of perfect health, and possess good constitutions.

Delabarre says, that a child, though it derives its being from weakly parents, may, by proper regimen, acquire a good constitution and temperament. M. MAHON, a French dentist, and author of considerable acumen and celebrity, affirms, that a person cannot be born with a good constitution, except those from whom he derives his being are in good health, and of that age when life is vigorous. But he admits, that a child coming from parents of the most perfect health, may have its constitution deteriorated by impure lactation: and that a child coming from weakly parents, may acquire a good constitution, though it will always bear about it certain signs of that which it had inherited—and thence, he deduces that it is possible to discover, by an examination of the teeth, any tendencies that may be lurking in the system. He has certainly studied the subject very attentively, and his remarks are worthy of consideration. If all he says is not true, many of his observations, we think, are susceptible of proof.

In treating upon the physiognomical indications of the

teeth, the last named author says : "Does the child derive its life from parents that are unhealthy? The enamel of its milk teeth will be bad ; the teeth, themselves, will be surcharged with a bluish vapor, and in a short time, will be corrupted by a humid and putrefying caries. When the parents are only weakly or delicate, the enamel of the primary teeth will have a bluish appearance, there will be a tendency in them to dry caries, which does not ordinarily make much progress, and seldom causes pain."

Again, he observes, "It was only by a determination to notice very accurately the differences which I remarked on the teeth of numerous individuals, that I obtained these first truths. In the first instance, they were little more than mere conjectures, but by being daily increased, have now become diagnostics, about the certainty of which, I flatter myself, I cannot be deceived. It affords me pleasure to give an account in this place of a part of the means which I employed to arrive at the point which was the object of my researches. When I perceived some signs, as for example, shadowy lines on the primary teeth, and those of replacement, of different children, I put all my application to work for the ascertainment of their cause, and when I believed I had found it, I interrogated their mothers, who generally confirmed the judgment I had formed. I then went on further ; after calculations that seemed to me highly probable, I ventured to declare the period at which a great crisis or disease had happened, and in such a month of pregnancy ; and I have had the satisfaction to find that I had conjectured correctly. My expectations, based upon the same procedure, have been crowned with success in *adults*, whose teeth, by the simple examination of them, have disclosed to me an advantage no less valuable than the first, namely, that of generally being able to tell, whether they were born of strong, weak, or aged parents ; and also, if the mother has had several children, whether they were among the last," etc.

That a person experienced in such researches, may, by an

examination of the deciduous teeth, tell whether the mother, during the latter periods of pregnancy, had enjoyed good or bad health, there is no question. But it is very doubtful whether much can be ascertained, by an inspection of the milk teeth, concerning the health of the mother previously to the time of the commencement of their solidification, for upon the manner in which this is effected, depends their appearance and physical condition. The density of a tooth may be told at a single glance by a practiced observer, and it is this and its color that are principally influenced by the condition of the system during their solidification. The shape of the teeth is determined by that of the jaws and pulps before the commencement of this process.

We are of opinion, therefore, that nothing positive, concerning the health of the mother during the first five or six months of pregnancy, can be learned from an inspection of the teeth of either dentition. From an inspection of those of the second, no information whatever in relation to it can be derived, and if Mahon was fortunate enough in some instances to tell what it had been at an earlier period, his prognosis could not have been founded upon any thing more than mere conjecture.

The teeth while in a pulpy state partake of the health of the organism generally. As that is healthy and strong, or unhealthy and weak, so will the elementary principles of which they are then composed, be of a good quality, or deteriorated, but after dentinification has commenced, the solid parts cease to be influenced by, or to obey the laws of the other parts of the body. If the general health be good at the time this process is going on, it will be evidenced in their density and color; if bad, in the looseness of their texture, etc.

This is a subject to which we have paid some attention, having for a long time been in the habit of carefully noting the differences in the appearance of the teeth of different individuals, and of both dentitions, and though we have been able to conjecture in some instances what had been the

state of the mother's health during the first months of pregnancy, candor compels us to confess, that we have never been able to find any signs in the peculiarity of their shape, size, density, or arrangement, that indicated it. But from the moment that that part of the formative process of these organs commences, which is not influenced by subsequent changes in the general economy, certain peculiarities of appearance are impressed upon them that continue through life, and about the certainty of the indications of which, in regard to the general health, we think there can be no doubt.

In commenting upon the views which M. Mahon advances upon this subject, Delabarre says,* "if he had thrown the light of repeated dissections upon them, he would have acknowledged, with Hunter, Blake, Maury, Fox and Bunon, that the secondary teeth do not begin to ossify until about the sixteenth month after birth, so that the good or bad health of the parents at the time of conception, cannot in any way affect the teeth of replacement, which are not formed until after the child comes into the world."

But, however vague and erroneous may be some of the opinions of Mahon, he has certainly advanced many that are correct, and from which, hints have been derived that have formed the foundation of some very valuable contributions to the science of the semeiology of the teeth.

LAVATER was laughed at and ridiculed for his enthusiastic belief in physiognomy, but the description which he gives, with a view to the illustration of his favorite science, of the physical conformation of the various parts of the face, head, and other portions of the organism of man, embrace signs, which, if applied to the study of semeiology, could hardly fail to lead to important results. Had the education and pursuits of this good and extraordinary man, fitted him for the investigation of this department of medical science, and had he entered into it with the same persevering ardor and

* Vide *Seimeitique Buccale*, p. 225.

zeal he did that of physiognomy, he would have erected for himself an equally enduring monument of fame, and would thus perhaps have contributed as much to the amelioration of the condition of his fellows, as he has done by his physiognomical researches. In fact, of the importance of this subject, he seems to have been fully aware; and, after acknowledging his ignorance, he says, the physiognomical and pathognomical semeiotica of health and disease ought to be treated on by an experienced physician, stating, that from the few observations which he had made, it was not difficult to discover the diseases to which an individual in health is most liable. He regards physiognomical semeiotics, founded upon the nature and form of the body, as of great importance to the medical practitioner, that he may be able to say to an individual in health, you may expect this or that disease some time in your life. Possessed of this knowledge, he would be able to prescribe the necessary preventives or precautions against such diseases as he is most liable to contract.

Among the signs which he notes as indicative of the temperament, he enumerates the shape, size and arrangement of the teeth, but from the physical characteristics of these organs, when considered separately from other parts of the mouth, we only learn what the innate constitution was; they cannot be relied upon as indices to the state of the health subsequently to the time of their solidification. Their own liability to disease, however, may be determined by their appearance, and with the signs, therefore, indicative of this, every dentist should be familiar, to enable him, when consulted with regard to the attention necessary to the preservation of these organs, to prescribe such precautionary measures as will secure them against the attacks of disease.

With regard, also, to the information to be derived from an inspection of the teeth, concerning the innate constitution, it has been well remarked by Delabarre, that physicians may derive much advantage in pointing out the rules

of domestic hygiene for the physical education of children ; for, says this eminent dentist, "can he admit of but one mode? Has he not, then, the greatest interest to be well assured of the innate constitution of each, for whom his advice is required, to enable him to recommend nutriment suited to the strength of its organs? Will he report only on a superficial examination of the face, its paleness, the color of the skin, all of which are variable? Will he not regard the repletion or leanness of the subject, the state of the pulse, &c.? Surely he will make good inductions from all these things ; but the minute examination of the mouth will give him, beyond doubt, the means of confirming his judgment ; for, besides what we already know of the teeth, the mucous membrane of the buccal cavity receives its color from the blood, and varies according to the state of that fluid." This is a matter which the observation of the dentist has an opportunity of confirming, almost every day ; and which, when taken in connection with the physical characteristics of the teeth, together with those of the salivary and mucous secretions of the mouth, constitute data, from which both the innate and present state of the constitutional health may be determined with accuracy and certainty.

The symptoms of actual disease have been minutely and repeatedly described, but the physiognomical signs by which the susceptibility of the human organism to morbid impressions is determined, and the kind of malady most liable to result therefrom, do not appear to be so well understood. "Whatever," says the author last quoted, "may be the knowledge which a practitioner may acquire of the changes a disease, or even a tendency to disease, may effect in the use of the functions of some organs, it is, at least, advantageous to be able to conjecture what has happened, in the whole of the system at another time. In fact, can a physician, when about to prescribe for a slight indisposition of a person whom he hardly knows, rely entirely upon the sabulous state of the tongue? Does not its aspect singularly

vary? Is it not notorious, that in certain persons it is always red, white, yellow or blackish? I, as well as others, have had occasion to make these observations on persons with whom it was always thus, but without their being subject to any of those indispositions that are so common in the course of life." These signs are as variable in sickness, as in health, and, consequently, can only be relied upon as confirmatory of the correctness of other indications which manifest themselves in other parts of the body.

The physical changes produced by, and characteristics of, disease, have been described, both by ancient and modern medical writers, but the works which have appeared upon this subject, do not comprise all that is necessary to be known. For example—if we examine the lips, tongue and gums of a dozen or more individuals who are regarded as in health, differences in their appearance and condition will be found to exist. The lips of some will be red, soft and thin; others red, thick, and of a firm texture; some will be thin and pale; others red on the inside and pale on the edges;—some are constantly bathed with the fluids of the mouth; others are dry, and these differences of appearance and condition are as marked on the tongue and gums as they are upon the lips, and are supposed to be attributable to the preponderance or want of existence in sufficient quantity of some one or more of the elementary principles of the organism. Hence, may be said to result the differences in temperament and susceptibility of the body to the action of morbid excitants.

The body, says Lavater, is composed, after an established manner, "of various congruous and incongruous ingredients." He also believes "that there is," to use the metaphor, "a particular recipe, or form of mixture, in the great dispensatory of God, for each individual, by which his quantity of life, his kind of sensation, his capacity and activity are determined; and that, consequently, each body has its individual temperament, or peculiar degree of irritability. That the humid and the dry, the hot and the cold,

“are the four principal qualities of the corporeal ingredients, is as undeniable as that earth and water, fire and air, are themselves the four principal ingredients.” “Hence,” he argues, “that there will be four principal temperaments; the choleric, originating from the hot; the phlegmatic, from the moist; the sanguine, from air; and the melancholic, from earth; that is to say, that these predominate in, or are incorporated with, the blood, nerves and juices, and indeed in the latter, in the most subtile, and almost spiritually active form. But it is equally indubitable to me, that these four temperaments are so intermingled that innumerable others must arise, and that it is frequently difficult to discover which preponderates; especially since, from the combination and interchangeable attraction of those ingredients, a new power may originate, or be put in motion, the character of which may be entirely distinct from that of the two or three intermingling ingredients.” The truth of these propositions will hardly be questioned, and their admission at once affords a satisfactory explanation of the differences in the susceptibility of different organisms to the attacks of disease.

Admitting the foregoing statement to be correct, we think it may be safely assumed, that if the quality and respective proportions of the materials furnished for the growth, repair and maintenance of the several organs of the body, be good, and in proper proportion, all the organs will be well formed and endowed with health, and, as a consequence, capable of performing their respective functions in a healthy manner. But if their elementary ingredients, to use an expression of the author from whom we have just quoted, be bad, their functions will be more or less feebly performed.

These materials are furnished by the blood.* From this fluid, each organ receives such as are necessary to its own

* Of the various writers who have treated upon this fluid, Magendie ranks deservedly high. He instituted a great variety of experiments upon animals, which go to prove, conclusively, that no one of its constituents can be dispensed with

particular organization. The blood, therefore, exercises an important influence upon the whole mechanism—determining the state of the health of all its parts, which, as Delabarre observes, is relative to its quality, and “that the general health results from that of all the system.” In order to this, harmony must exist between all the organs, but in consequence of the great variety and intermingling of temperaments it rarely does, except, perhaps, in those in whom the sanguine predominates, and who have not become enervated by irregular and luxurious living. Even when it does exist, we are by no means certain that it will continue to do so ; for exposed as the body is to a thousand causes of disease, its functional operations may, at almost any moment, become disturbed. Among the civilized nations of the earth, the peasantry of Great Britain, probably, possesses as good constitutional temperaments as are anywhere to be found : and yet, with these people, we are told, that although the sanguinous predominates in a majority of cases, it is combined and intermingled, in a greater or less degree, with others.

In all of these modifications the blood plays an important part : it determines the temperament of the individual, and as a consequence, the physical condition of all the tissues of the body subject to the general laws of the economy. But the dependency of the solids upon this fluid is only mutual ; it, also, is dependent upon them, and the condition of the one is relative to that of the other. The solids, if we may be permitted the use of the metaphor, are the distillery of the fluids, while they, in turn, nourish, repair, and maintain the solids. A change, then, in the condition of one, is followed by a corresponding change in the condition of the other. If the blood be of an impure quality, or any of the ingredients entering into its composition exist in too great or too small quantity, it will fail to supply the solids

without manifest and serious injury to the whole organism—and that, it is dependent for its living principles upon the motion that is given to it in the circulatory system.

with the materials necessary to the healthful performance of their functions, and, if not actual disease, a tendency to it, will be the result. And, again, the purity of the blood is dependent upon the manner in which the solids perform their offices. While, therefore, duly appreciating the importance of this fluid, and its existence in a pure state, to the general health of the economy, we cannot ascribe to it, regardless of the functions of the solids, a controlling influence over the organism.

To distinguish all the nice and varied shadings of temperament, or states of the constitutional health, by the physiognomical appearances of the body, is perhaps impossible, or can only be done with great difficulty, and by those who have been long exercised in their observance; but to discover that which predominates is not so difficult a matter, and the indications are nowhere more palpably manifested than in the mouth. By an inspection of the several parts of this cavity, together with its fluids and the earthy matter found upon the teeth, we repeat, inductions may be made, not only with regard to the innate constitution, but also with regard to the present state of health, serviceable both to the dental and medical practitioner; and, in the further prosecution of this inquiry, we shall endeavor to point out some of the principal of the indications here met with—the appearances by which they are distinguished, and to offer such other general reflections as the subject may, from time to time, seem to suggest.

CHAPTER SECOND.

PHYSICAL CHARACTERISTICS OF THE TEETH.

MOST dental physiologists have observed the marked differences that exist in the appearances of the teeth, gums, lips, tongue, and secretions of the mouth of different individuals; and of that earthy substance, (commonly called tartar,) deposited in a greater or less abundance, on the teeth of every one, and though all may not have sought their etiology, many have had occasion to notice, at least, their local indications, and to profit from the information which they have thus obtained. Nor have they failed to observe that the volume, color, length and arrangement of the teeth vary, and that these are indicative of their susceptibility to disease.

There are five principal classes or descriptions of teeth, each of which differs, in some respects, from the others.

Class First.—The teeth belonging to this class are white, with a light cream colored tinge near the gum, which becomes more and more apparent as the subject advances in age—of a medium size, rather short than long; those of each class of uniform dimensions, and very hard. This description of teeth is most frequently met with in persons of sanguinous temperaments, or, at least, those in whom this predominates; they rarely decay, and are indicative, if not of *perfect* health, of a state which bordered very closely on it at the time of their dentinification.

This description of teeth is, at least, occasionally found among persons of all nations. They are very common, especially in the middle classes of the inhabitants of England,

Ireland and Scotland. They are also frequently met with in some parts of the United States, the Canadas, the mountainous districts of Mexico, and so far as we have had an opportunity of informing ourself, in France, Russia, Prussia and Switzerland. Those who have them, usually enjoy excellent health, and are seldom troubled with dyspepsia or any of its concomitants. It is this kind of teeth, which Lavater says, he has never met with, except in "good, acute, candid, honest men," and of whose possessors, it has been remarked that their stomachs are always willing to digest whatever their teeth are ready to masticate.

In confirmation of what has before been said with regard to the influence which the state of the constitutional health at the time of the solidification of the teeth, exerts upon the susceptibility of these organs to morbid impressions, it is only necessary to mention the fact, well known and frequently alluded to, of the early decay of a single class, or a pair of a single class of teeth, in each jaw, while the rest, possessing the characteristics just described, remain sound through life. Thus when it happens, that a child, of excellent constitution, is affected with any severe disease, the teeth which are at the time receiving their earthy salts, are found, on their eruption, to differ from those which have received their solid material at another time, when the operations of the body were healthily performed. Instead of having white, smooth and uniform surface, they have a sort of chalky aspect, or are faintly tinged with blue, and are rougher and less uniform in their surfaces. Teeth of this description are very susceptible to the action of corrosive agents, and as a consequence, rarely last long.

But, not willing to rest the correctness of these views upon mere hypothesis, we, in a great number of instances, where we have seen teeth thus varying in their physical appearance, taken pains to inquire of those who had had an opportunity of knowing the state of the general health of the individuals, at the different periods of dentinification, and in every case where we have been able to procure

the desired information, it has tended to the confirmation of the opinion here advanced. Nor have we neglected to improve the many opportunities that have presented, in the course of a somewhat extended professional career, of making these observations.

Although the operations of the economy are so secretly carried on, that it is impossible to comprehend their mechanism fully, it is known that the phenomena resulting therefrom, are influenced and modified by the manner in which they are performed. If they are deranged, the blood, from which the earthy materials forming the basis of all the osseous tissues, are derived, is deteriorated, and furnishes these salts in less abundance and of an inferior quality. Hence, teeth that solidify when the system is under the influence of disease, do not possess the characteristics necessary to enable them to resist the assaults of corrosive agents, to which all teeth are more or less exposed, and which rarely affect those that receive their solidifying ingredients from pure blood.

The calcareous salts of these organs are furnished by the red part of this fluid, and the gelatine is derived from the white or serous part;—"whence," as Delabarre remarks, "it results that the solidity of these bones vary according as the one or the other of these principles predominates," and the relative proportions of these are regulated by the state of the blood at the time the teeth are undergoing solidification. In healthy subjects, the blood is composed of about four parts of crassamentum, or clot, and one of serum, but the relative proportions of these are not always the same. Disease tends to diminish the red, and to increase the white or serous part of this fluid. Sometimes the serum forms more than one-half, and as this abounds at the time of the solidification of the teeth, they will be soft in their texture, and liable to decay.

The researches of DUHAMEL show, that bones acquire solidity no faster than the parts which are about to ossify become charged with red blood. The experiments of HAL-

LER are also confirmatory of this opinion. And Delabarre, in remarking upon the dentinification of the teeth, says, "the superficial layer of the pulp reddens before it ossifies, whilst all below is entirely white ; soon another layer reddens, is ossified, and then whitens, and so on, successively."

The increase of density which the teeth continue through life very gradually to acquire, may seem to militate somewhat against this theory, as the fluid conveyed to the dentine subsequent to solidification, is not so much as even tinged with red. But, that these organs are capable of being injected with red blood, has been satisfactorily shown ; and if teeth are capable, under any circumstances, of being injected with red blood, is it unfair to presume, that a portion of some of the red globules may become so broken down and reduced as occasionally to be carried into the vessels or tubuli of the dentine by the impetus ordinarily given to this fluid by the circulatory apparatus. The author is of the opinion that it is not, and that it is in this way that the increase of density which the teeth acquire is to be accounted for. A sufficient quantity of these broken globules, he would suppose, might be conveyed through the vessels of the dentine, to effect the very trifling and almost imperceptible increase of density it acquires, subsequently to dentinification. This hypothesis, he is aware, does not accord with the views of Hunter in regard to the organization of the teeth, nor with those of several modern European writers on odontology, who maintain that these organs are not endowed with vascularity, but the incorrectness of this doctrine has, we think, been satisfactorily shown.

Class Second.—Having digressed thus far, we shall now proceed to notice the teeth belonging to the second class. They have a faint azure blue appearance; are rather long than short; the incisors are generally thin and narrow; the cuspids are usually round and pointed; the bicuspids and molars small in circumference, with prominent cusps and

protuberances upon their grinding surfaces. In some cases, the lateral incisors are very small and pointed.

Teeth possessing these characteristics are usually very sensitive, more easily acted upon by corrosive agents than teeth of the first class, and to the ravages of which, unless great attention is paid to their cleanliness, they often fall early victims. They are more frequently affected with atrophy, or have upon their surfaces white, brown or opaque spots, varying in size and number; several are sometimes found upon a single tooth, and in some instances every tooth in the mouth is more or less marked with them.

But this is not the only description of teeth liable to be affected with this disease. These spots are occasionally met with on teeth of every degree of density, shape, shade and size, but they are, probably, more frequently seen on these than those first described, and, besides, it often happens that they are affected with erosion on emerging from the gums, and sometimes, so badly as to place both their restoration and preservation beyond the reach of art. This species of erosion, or that which occurs previous to the eruption of the teeth, is caused by some diseased condition of the fluid which surrounds them before they appear above the gums, and is denominated congenital.

Teeth like those now under consideration, are indicative of a weakly, innate constitution—of a temperament considerably removed from the sanguinous—and of blood altogether too serous to furnish materials, such as are necessary for building up a strong and healthy organism. They are more common to females than males, though many of the latter have them. They are met with among people of all countries, but more frequently among those who reside in sickly localities, and with individuals whose systems have become enervated by luxurious living. In Great Britain, they are more rare than in the United States, and those who have them, seldom attain to a great age. Nevertheless, some, under the influence of a judicious regimen, and a salubrious climate, though innately delicate, do acquire a good

constitution, and live to a great age, while the teeth, less fortunate, except the most rigid and constant attention is paid to the use of the means necessary for their preservation, generally soon fall early victims to the ravages of disease.

Class Third.—The teeth of this class, though differing in many of their characteristics from those last described, are, nevertheless, not unlike them in texture and susceptibility to disease. They are larger than teeth of the first or second class; their faces are rough and irregular, with protuberances, rising, not only from the grinding surfaces of the bicuspid and molars, but also, not unfrequently, from their sides, with correspondingly deep indentations. They have a muddy white color. The crowns of the incisors of both jaws are broad, long and thick. The posterior or palatine surfaces of those of the superior maxillary are rough, and usually deeply indented. In the majority of cases, their arrangement is quite regular, though frequently inclined to project. The alveolar ridge usually describes a broad arch. The excess in size, both here and in the teeth, seems to consist more of gelatine than calcareous phosphate. This description of teeth decay readily, and in some instances appear to set at defiance the resources of the dentist. They are liable to be attacked at almost every point, but more particularly in their indentations and approximal surfaces.

The author is acquainted with a family, consisting of seven or eight members, most of whom are adults, all having this sort of teeth. The most thorough attention has been paid by each, and yet all have lost most of their teeth. They are usually first attacked in their approximal surfaces and indentations, but neither their labial faces nor most prominent points are exempt from caries. No sooner than its progress is arrested in one place or part, than it appears in another. The author has had occasion to fill a single tooth in as many as four, five and even six different places,

and in this way, though his efforts at the preservation of a considerable number have proved unavailing, he has been able to save many of them. But it is not necessary to particularise cases. Every dentist has seen teeth of this description.

The corrosive properties of the fluids of the mouth, however, are sometimes so changed by an amelioration of the constitution, that notwithstanding the great susceptibility of the teeth to disease, they are sometimes preserved to a late period of life, or until the general health relapses into its former, or some other unfavorable condition. This has happened in several instances that have come under the author's immediate observation, and it should be borne in mind, that the solvent qualities of these juices are influenced by the state of the constitutional health.

Class Fourth.—Teeth of this class usually have a white chalky appearance, are unequally developed, and of a very soft texture. They are easily acted upon by corrosive agents, and like the teeth last noticed, generally fall speedy victims to disease, unless great care is taken to secure their preservation.

Persons who have teeth such as described in classes three and four, generally have what Laforge calls, lymphaticoscerous temperaments. Their blood is usually pale, the fluids of the mouth abundant, and for the most part exceedingly viscid. They do not have that white frothy appearance observable in healthy sanguinous individuals.

As teeth that are neither too large nor too small, and that have a close compact texture, and are slightly tinged with yellow, are indicative of an innately good constitution, whatever it may be at the present time, so those which are long, narrow, and faintly tinged with blue, as well as those that greatly exceed the ordinary size, and that are irregular in shape, and have a rough, muddy appearance, furnish assurance of a constitution originally bad. The first of the latter descriptions of teeth are more fre-

quently met with among females than males, and among those of strumous habits, than those in whom this diathesis does not exist.

Class Fifth.—The teeth belonging to this class are characterized by whiteness and a pearly gloss of the enamel. They are long, and usually small in circumference, though sometimes well developed. They are regarded by many as denoting a tendency to phthisis pulmonalis, and are supposed by some to be very durable, but the author has observed that individuals who have this sort of teeth, when attacked by febrile or any other form of disease having a tendency to alter the fluids of the body, are very subject to tooth-ache and caries, and that when this condition of the general system is continued for a considerable length of time, that the teeth, one after another, in rapid succession, crumble to pieces.

It would seem from this circumstance, that the fluids of the mouth of subjects of strumous habits, if free from other morbid tendencies, are less prejudicial to the teeth than they are in most other constitutions, and the author is of the opinion that it is owing to this that they are so seldom attacked by caries. M. Delabarre believes, that caries supervenes to this disease, and is a consequence of the general debility engendered by it. He says, however, that “the patient generally dies before the central ganglion arrives at that state in which its properties are changed.”

Now, this is directly opposed to all observation on the subject, for it is well known, that teeth are less affected by this disease than almost any other, and it is unfortunate for the doctrine, which he in another place advocates, that the solid tissue of these organs is softened by the arteries ceasing to supply it with calcareous materials, that he should have resorted to this argument. Its absurdity is rendered apparent by his own showing, and that, too, in the paragraph succeeding the one in which the argument is used. He says, “whatever may be the diseased condition of the

teeth, they may be examined as unexceptionable evidence, that will inform us whether the patient owes his present state of health to a predisposition, or whether having supervened during the course of his life, it depends on an accidental cause."

If the state of the health, subsequent to dentinification, were capable of diminishing or increasing the density of these organs we could learn nothing by inspection of the primordial constitution. Nor would we, therefore, be able to determine whether the present state of health was the result of constitutional predisposition, or of some other cause; for, if they were subject to changes, like other parts of the body, their physical condition might be different to-day from what it was yesterday, and a diagnosis, founded upon the appearance of the teeth, would be nothing more than mere vague conjecture.

But, although Delabarre is in many things somewhat inconsistent, many of his views are correct, and few men have contributed more largely, by observation and experience, to the advancement of the science of the teeth, than he has done.

In speaking of persons who have teeth, which, though beautiful, from having smooth and apparently polished surfaces, present shades intermixed with a dirty white, he says, they "have had alternations of good and indifferent health during the formation of the enamel. These teeth," he continues, "ordinarily have elongated crowns, and many present marks of congenital atrophy." Again, he observes, "teeth of this sort deceive us by appearing more solid than they are; they remain sound until about the age of fourteen or eighteen; then, at this period, a certain number of them decay, especially when in infancy the subject was lymphatic, and continues to be so in adolescence. This description of teeth is frequently met with among the rich classes, where children born feeble, reach puberty only by means of great care, and, consequently, owe their existence only to the unremitting attention of their parents, and the strengthening

regimen that the physician has caused them constantly to pursue. Having reached the eighteenth or twentieth year, their health is confirmed, but the mucous membranes ever after have a tendency to be affected ; the redder color of the mouth, more especially its interior, and that of the lips, and the upper part of the palate, which, by degrees, discovers itself as the subject gradually advances in existence, showing its ameliorated condition. It is thus, that numerous persons, having gained a sanguinous temperament, would deceive us, if it were not that some marks of erosion are seen on the masticating surfaces of the first permanent molars, which informs us that the present health is the result of amelioration."

There are other cases in which the teeth are of so inferior a quality, that they no sooner emerge from the gums than they are attacked and destroyed by caries, while the subjects who possess them, are enabled, by skillful treatment to overcome the morbid constitutional tendencies, against which, during the earlier years of their existence, they had to contend, and eventually, to acquire excellent health. But in forming a prognosis, it is essential to ascertain whether the general organic derangement which prevented the teeth from being well formed, and thus gave rise to their premature decay, is hereditary, or whether it has been produced by some accidental cause subsequent to birth. The procurement of health in the former case, will be less certain than in the latter, for when the original elements of the organism are bad, the attainment of a good constitution is more difficult.

Persons of sanguino-mucous temperaments, having suffered in early childhood from febrile or inflammatory diseases, often have their teeth affected with what Duval calls the decortivating process, (denudation of their enamel,) resulting, no doubt, from the destruction of the bond of union between it and the dentine.

There are other characteristics which the teeth present in shape, size, density and color, and from which valuable in-

ductions might be made, both with regard to the innate constitution and the means necessary to their own preservation; but as the limits prescribed to this part of our subject will not admit of their consideration, we shall conclude by observing, that the appearances of these organs vary almost to infinity. Each is indicative of the state of the general health at the time of their dentinification, and of their own physical condition and susceptibility to disease.

CHAPTER THIRD.

PHYSICAL CHARACTERISTICS OF THE GUMS.

LITTLE can be ascertained concerning the innate constitution from an inspection of the gums. Subject to the laws of the general economy, their appearance varies with the state of the general health and the condition and arrangement of the teeth. Although the proximate cause of disease in them may be regarded as local irritation, produced by depositions of tartar upon the teeth, or decayed, dead, loose or irregularly arranged teeth, or a vitiated state of the fluids of the mouth, resulting from general organic derangement, or any or all of the first mentioned causes, their susceptibility to morbid impressions is influenced to a considerable extent by the constitutional health ; and the state of this determines, too, the character of the morbid effects produced upon them by local irritants. For example, the deposition of a small quantity of tartar upon the teeth, or a dead or loose tooth, would not, in a healthy person, of a good constitution, give rise to anything more than slight increased vascular action in the margin of the gums in contact with it ; while in a scorbutic subject, it would cause them to assume a dark purple appearance a considerable distance around, to become swollen and flabby, to separate and retire from the necks of the teeth, or to grow down upon their crowns, to ulcerate and bleed from the slightest injury, and to exhale a fetid odor. In proportion as this disposition of body exists, their liability to be thus affected is increased ; and it is only among constitutions of this kind that that peculiar preternatural morbid growth, by which the whole of the crowns

of the teeth sometimes become almost entirely imbedded in their substance, takes place.

But, notwithstanding the dependency of the condition of the gums upon the state of the constitutional health, they are occasionally affected with sponginess and inflammation in the best temperaments, and in individuals of uninterrupted good health. The wrong position of a tooth, by causing continued tension of the gums investing its alveolus, sooner or later gives rise to a sort of chronic inflammation in them and the alveolo-dental periosteum, and gradual wasting of their substance about the mal-placed organ. Tooth-ache, too, from whatever cause, often produces the same effects, and the accumulation of salivary calculus upon the teeth, however small the quantity, is likewise prejudicial.

All of these may occur independently of the state of the general health. A bad arrangement of the best constituted teeth, and tooth-ache may be produced by a multitude of accidental causes, independently of the functional operations of other parts of the body.

While, therefore, the appearance and physical condition of this peculiar and highly vascular structure are influenced in a great degree by habit of body, they are not diagnostics that always, and with unerring certainty, indicate the pathognomic state of the general system. It can, however, in by far the larger number of cases, where the gums are in an unhealthy condition, be readily ascertained whether the disease is altogether the result of local irritation, or whether it is favored by constitutional tendencies.

In childhood, or during adolescence, when the formative forces of the body are all in active operation, and the nervous susceptibilities of every part of the organism highly acute, the sympathies between the gums and other parts of the system, and particularly the stomach, are, perhaps, greater than at any other period of life. The general health, too, at this time, is more fluctuating, and with all the changes this undergoes, the appearances of the gums vary. Moreover, there are operations carried on beneath and within

their substance, which are almost constantly altering their appearance and physical condition—and which, being additionally influenced by various states of health and habits of body, it may readily be conceived that those met with in one case, might be looked for in vain in another.

Having arrived at that age when all the organs of the body are in full vigor of maturity, and not under the debilitating influences to which they are subject during the earlier periods of life, the gums participate in the happy change, and as a consequence, present less variety in their characteristics. The general irritability of the system is not now so great, the gums are less susceptible to the action of irritating agents, and as a consequence, less frequently affected with disease; but as age advances, and the vital energies begin to diminish, the latent tendencies of the body are re-awakened, and they are again easily excited to morbid action.

In the most perfect constitutions, and during adolescence, they present the following appearances. They have a pale rose-red color, a firm consistence, a slightly uneven surface; their margins form along the outer surfaces of the dental circle beautiful and regular festoons, and the mucous membrane, here, as well as in other parts of the mouth, has a fresh, lively, roseate hue.

The time for the moulting of a primary tooth is announced some weeks before it takes place, by increased redness and slight tumefaction of the edges and apices of the gums surrounding it. The eruption of a tooth, whether of the first or second set, is also preceded by similar phenomena in the gums through which it is forcing its way, and these will be more marked as the condition of the system is unhealthy, or as the habit of body is bad.

If the health of the subject continues good, and the teeth are well arranged, and the necessary attention to their cleanliness be strictly observed, the characteristics just enumerated will be preserved through life, except there will be a slight diminution of color in them, after the age

of puberty until that of the climacteric period of life, when they will again assume a somewhat redder appearance. But if the health of the subject becomes impaired, or the teeth be not regularly arranged, or wear off, or are not kept free from all lodgments of extraneous matter, their edges, and particularly their apices, will inflame, swell, and become more than ordinarily sensitive.

The gradual wasting or destruction of the margins of the gums around the necks of the teeth, which sometimes takes place in the best constitutions, and is supposed by some to be the result of general atrophy, is ascribable, we have no doubt, to some one or other of these causes—favored, perhaps, by a diminution of vitality in the teeth, whereby they are rendered more obnoxious to the more sensitive and vascular parts within which their roots are situated. That these are the causes of the affection, (for it is evidently the result of diseased action in the gums,) is rendered more than probable, by the fact, that it rarely occurs with those who, from early childhood, have been in the regular and constant habit of thoroughly cleansing their teeth from four to five times a day.

Mr. Bell, however, while he thinks it may occasionally be an "indication of a sort of premature old age," does not believe it can "always be thus accounted for, as it is sometimes seen in young persons," and "doubtless arises," he says, "from the same cause as those presently to be considered," (alluding to what he afterwards says upon the same subject,) "as originating a similar loss of substance in these parts, when attended with more or less of diseased action." We cannot, for reasons already assigned, concur with him in opinion that it "occasionally takes place without any obvious local or constitutional morbid action."

Although possessed of a good constitution, a person may, by intemperance, debauchery, or long privation of the necessary comforts of life, or protracted febrile or other severe kinds of disease, have his assimilative and all the other organs of the body so enervated as to render every part of

the system highly susceptible to morbid impressions of every sort, but still, this general functional derangement rarely predisposes the structure now under consideration, to any of the more malignant forms of disease occasionally known to attack it in subjects possessed of less favorable innate constitutions. The margins of the gums may inflame, become turgid, ulcerate, and recede from the necks of the teeth, and the whole of their substance be involved in an unhealthy condition, but they will seldom be attacked with scirrhus or fungous tumors, or bad conditioned ulcers, or affected with preternatural morbid growths, and in the treatment of their diseases, we can always form a more favorable prognosis in persons of this description, than those coming into the world with some specific morbid tendency.

But, the occurrence of severe constitutional disease, even in these subjects, is followed by increased irritability of the gums, so that the slightest cause of local irritation gives rise to an afflux of blood to and stasis of this fluid in their capillaries.

The teeth of persons thus happily constituted, are endowed with characteristics, such as have been represented as belonging to those of the best quality. They are of a medium size, both in length and volume, white, compact in their structure, generally well arranged, and seldom affected with caries.

Another constitution is observed, in which the gums, though partaking somewhat of the characteristics just described, differ from them in some particulars. Their color is of a deeper vermilion; their edges rather thicker, their structure less firm, and their surface not so rough, but more humid. The mucous membrane has a more lively and animated appearance. They are more sensitive and more susceptible to the action of local irritants, with morbid tendencies more increased by general organic derangement, than when possessed of the appearances first mentioned.

When in a morbid condition, the disease, though easily

cured by proper treatment, is, nevertheless, more obstinate, and when favored by constitutional derangement, assumes a still more aggravated form. Their predisposition to disease is so much increased by long continued disturbance of the general system, and especially during youth, and by febrile or inflammatory affections, that not only their margins, but their whole substance, sometimes becomes involved in inflammation and sponginess, followed by ulceration of their edges, and recession from the necks of the teeth, which, in consequence, loosen, and often drop out. But gums of this kind, like those first described, seldom grow down upon the crowns of the teeth. Neither are they very liable to be attacked with scirrhus or fungous tumors, or any form of disease resulting in sanious or other malignant conditioned ulcers. Indeed, with diseases of this kind, they are not, perhaps, ever affected, except in those cases where every part of the body has become exceedingly depraved by intemperance, debauchery, or some other cause.

The teeth of those whose gums are of this description, if well arranged and kept constantly clean—and, if the secretions of the mouth be not vitiated by general disease, will, in most cases, remain healthy through life.

It is only among sanguinous persons that this description of gums is met with, and the teeth of subjects of this kind are generally of excellent quality, and though more liable to be attacked by caries than those first noticed, they are seldom affected with it.

In sanguino-serous and strumous subjects, the gums are pale, and though their margins are thin and well festooned, often exude, after the twenty-fifth or thirtieth year, a small quantity of muco-purulent matter, which, on pressure, oozes from between them and the necks of the teeth. Their texture is usually firm, and they are not very liable to become turgid. They often remain in this condition to a late period of life, without undergoing any very perceptible change. Their connection with the necks of the teeth and

alveolar processes appears weak, but they rarely separate from them.

In remarking upon individuals having such constitutions, M. Delabarre says, that if they "abuse their physical powers," by an injudicious regimen, or too much study, they become enervated and "are subject to chronic sanguinous obstructions of the capillaries of the lungs, and to profuse hemorrhages." Dyspepsia and diseases in which the primæ viæ generally is more or less involved, and chronic hepatitis, are not unfrequent, and are indicated by increased irritability, and sometimes, a pale yellowish appearance of the gums. In jaundice, the yellow serosity of the blood is very apparent in the capillaries of this structure.

These constitutions are more common to females than males, to the rich than the poor, and to persons of sedentary habits than to those who use invigorating exercise. If at any time during life the health is ameliorated, the gums assume a fresher and redder appearance, and the exudation of muco-purulent matter from between them and the necks of the teeth ceases.

In mucous dispositions, the gums have a smooth, shining appearance, and are rather more highly colored than the preceding. Their margins, also, are thicker, more flabby, and not so deeply festooned; they are more irritable, and, consequently, more susceptible to morbid impressions.

If, to this disposition, there be combined a scorbutic or scrofulous tendency, the gums during early childhood, in subjects which, from scanty and unwholesome diet, have become greatly debilitated, are liable, besides the ordinary forms of disease to another, characterized by their separation from, and exfoliation of, the alveolar processes—accompanied by a constant discharge of sanies. This form of disease, however, though peculiar to childhood, and wholly confined to the indigent, is by no means common.

These constitutions are rarely met with, except among persons who live in cellars, and damp and closely confined rooms in large cities, and in low, damp, and sickly districts

of country. The mucous membrane in subjects of this kind is exceedingly irritable, and secretes a large quantity of mucus.

In alluding to this species of disposition, M. Delabarre says, "in children, the skin is ordinarily white and tender; nevertheless, it is sometimes brown and wrinkled. They are usually fragile and weak; their blood is pale, their nutrition is imperfectly effected. In females, the vertebral column is disposed to curve about the age of puberty, because," says he, "at this period, the vital energies are principally directed towards the uterus, and, in consequence, although so very necessary in the osseous system, they appear to be weak.

"The number of observations that I have collected during my practice in the city, and in several public institutions, have confirmed me in the opinion, that it is in this constitution, especially, (alluding to the mucous,) that the children of whom we have just spoken, are met with. The *organic life* in them has so little energy, that a local cause on a certain point, operates with greater activity than it would otherwise do, sensibly diminishing the assimilative force of almost all the others. It is also probable, that the development of ganglionic obstructions during dentition, are, many times, owing to the diminution of the sensibility in the lymphatics.

"We may also remark," says he, "that, their skin being very susceptible, the sympathy established between it and the mucous membranes, renders individuals of this kind very liable to contract rheums, and gastric and intestinal affections; they are, likewise, subject to easy night sweats, and vomitings of a seromucous fluid," etc.

Persons even thus unhappily constituted, do, sometimes, by change of residence and judicious regimen, acquire tolerably good constitutions. Little advantage, however, is derived from these, unless they are had recourse to before the twenty-fifth or thirtieth year of age, though they may prove beneficial at a much later period.

The gums, in scorbutic persons, have a reddish brown color; their margins are imperfectly festooned, and thick; their structure rather disposed to become turgid, and ever ready, on the presence of the slightest cause of local irritation, to take on a morbid action. When thus excited, the blood accumulates in their vessels—where, from its highly carbonized state, it gives to the gums a dark, purple, or brown appearance; they swell, and become spongy and flabby, and bleed from the slightest touch. To these symptoms, supervene the exhalation of a fetid odor, the destruction of the bond of union between them and the necks of the teeth, suppuration and recession of their margins from the same—gradual wasting of the alveolar cavities, loosening, and not unfrequently, the loss of several, or the whole of the teeth. These are the most common results, but, sometimes, they take on other and more aggravated forms of diseased action. Preternatural prurient growths of their substance, fungous and scirrhus tumors, ichorous and other malignant, ill-conditioned ulcers, etc.

The occurrence of alveolar abscess in dispositions of this kind is often followed by necrosis and exfoliation of portions of the maxillary bone, and the effects which result to the gums are always more pernicious than in habits less depraved.

The development of the morbid changes which take place in this structure, even in subjects of this kind, while the character of the disease is influenced, if not determined, by a specific constitutional tendency, is, nevertheless, referable to local irritation as the immediate or proximate cause, and, were this the proper place, we could cite numerous cases tending to establish the truth of this opinion.

In scrofulous habits, the gums have a pale bluish appearance, and when subjected to local irritation, they become flabby, exhale a nauseating odor, detach themselves from the necks of the teeth, and their apices grow down between these organs. The blood circulates in them languidly, and debility seems to pervade their whole substance. They are exceedingly irritable, and not unfrequently take on aggra-

vated forms of disease, and, as often happens to this, as well as to the preceding habit, there are combined tendencies which favor the production of ill-conditioned tumors and ulcers.

The indications furnished by the gums during the existence of a mercurial diathesis of the system, are, morbid sensibility, increased vascular and glandular action, foulness, bleeding from the most trifling injuries, pale bluish appearance of their substance, turgidity of their apices and sloughing. The effects, however, resulting to these parts from the use of mercury differ in different individuals according to the general constitutional susceptibility, the quantity taken into the system, and the length of time its use has been continued. In persons of very irritable habits, a single dose will sometimes produce ptyalism, and so increase the susceptibility of the gums, that the secretions of the mouth, in their altered state, will at once rouse up a morbid action in them.

The effects of a mercurial diathesis upon these parts, is not unfrequently so great as to result in the loss of the whole of the teeth. But with these effects both the dental and medical practitioner are too familiar to require any further description.

Finally, we would observe, that the indications of the several characteristics to which we have now briefly alluded, may not be correct in every particular, and there are others which we have not mentioned; yet we think they will generally be found true. As a general rule, persons of a full habit, though possessed of mixed temperaments and in the enjoyment of what is usually called good health, have gums well colored, with rather thick margins, and very susceptible to local irritation. With this description of individuals, inflammation, turgidity, and suppuration of the gums are very common. To prevent these effects, constant attention to the cleanliness of the teeth is indispensable.

Professor Schill says, the "gum is pale in chlorosis and anæmia; of a purple red color before an active hemorrhoi-

dal discharge, and in cases of dysmenorrhœa ; of a dark red color, spongy, and bleeding readily in scurvy and diabetes mellitus, and after the use of mercury. Spongy growths indicate caries of the subjacent bone.”*

Regular periodical bleedings of the gums in dysmenorrhœa, and particularly in scorbutic and mucous subjects, are not unfrequent, nor in any case where they are in a turgid condition.

Spongy growth of the gums in scorbutic and scrofulous persons, often result from irritation produced by decayed teeth, and are not, therefore, always to be regarded as an indication of caries of the subjacent bone.

Dr. T. Thompson of London, says, that the reflected margin of the gums of a large majority of phthisical patients, is deeper in color, usually presenting a vermilion tint, than the other portions.†

Mr. George Waite says, “a change of residence to a damp climate will often rouse up in the gums a great degree of vascularity. In the damp places of England and Ireland the appearances which the gums present are of a turgid and vascular nature. In the damp countries of France, these conditions of the gums run a much greater length from the circumstance of the difference in the constitutions of the two nations. In the damps of Germany and Switzerland, persons also lose their teeth early in life, the climate engenders malaria and low fevers, enfeebles the power of digestion, and brings on rheumatic affections with languor and general constitutional debility.”

Of the correctness of Mr. Waite’s observations there can be no question, and they go to establish what has been said in regard to the predisposing cause of disease in the gums—namely, that the enervation of the vital powers of the body, from whatever cause produced, increases their susceptibility to morbid impressions.

CHAPTER FOURTH.

PHYSICAL CHARACTERISTICS OF SALIVARY CALCULUS.

THE color, consistence, and quantity of salivary calculus or tartar, as it is most commonly called, varies in different temperaments, and upon all of which, the state of the general health exercises considerable influence. The characteristics of this substance, therefore, furnish diagnoses, important both to the physician and dentist. Their indications are in many cases less equivocal than the appearances of any other part of the mouth; but, like those of the gums, should not perhaps, be alone relied upon. It is necessary to interrogate every part from which information can be derived concerning the pathological condition of the several organs of the body.

Salivary calculus is composed of earthy salts and animal matter. Phosphate of lime and fibrina, or cartilage, are its principal ingredients; a small quantity of animal fat, however, enters into its composition, and the relative proportions of its constituents vary according as it is hard or soft, or as the temperament of the individual from whose mouth it is taken, is favorable or unfavorable to health; hence it is, that the analyses that have been made of it by different chemists, differ. No two give the same result.

The black, dry tartar, deposited around the necks of the teeth of such only as have good constitutions, is never in large quantity—is dissolved in muriatic acid with difficulty, while the dry light brown tartar found upon the teeth of bilious persons, dissolves more readily in it; but the soft white tartar, found upon the teeth of individuals of mucous

temperaments, is scarcely at all soluble in the acids, but is readily dissolved in the alkalies.*

All persons are subject to salivary calculus, but not alike; it collects on the teeth of some in larger quantities than on those of others, and its chemical and physical characteristics are exceedingly variable. It is, sometimes, almost wholly composed of calcareous ingredients; at other times, these constitute but about one-half, or little more than one-half of its substance—the remainder being made up of animal matter. Nor is its color more uniform. Sometimes it is black, at other times it is of a dark, pale, or yellowish brown, and in some instances it is nearly white. It also differs in density. In the mouths of some it has a solidity of texture nearly equal to that of the teeth themselves, in others, it is so soft that it can be scraped from the teeth with the thumb or finger nail. The black kind is the hardest, the white the softest, and its density is increased or diminished as it approaches the one or the other of these colors.

Salivary calculus collects in very small quantities on the teeth of persons possessed of the most perfect constitution, and, even on these it is seldom found, except on the inner surfaces of the lower incisors next the gums. It is then black, or of a dark brown; very dry, and almost as hard as the teeth, to which it adheres with great tenacity.

It rarely happens that any unpleasant effects are produced by the presence of this kind of tartar upon the teeth. The general health is never affected by it, and the only local injury that results from it, is slight turgidity of the edge of the gums in immediate contact with it.

The indications, therefore, of this description of tartar, are favorable, both with regard to the teeth, gums and organism generally. The teeth upon which it is found are of an excellent quality and rarely affected by caries. They have the characteristics represented as belonging to the best kind

* See M. Delabarre's *Traité de la Seconde Dentition*.

and teeth of this description are only found among persons having good innate constitutions.

There is another kind of black tartar, differing from this in many particulars. It is found in the mouths of those having good innate constitutions, but whose physical powers have been enervated by privation of the necessary comforts of life, or disease, or intemperence and debauchery, and most frequently by the last. It is found in large quantities on the teeth opposite the mouths of the salivary ducts; it is exceedingly hard, and agglutinated so firmly to the organs, that it is removed with great difficulty; it is very black; has a rough and uneven surface, is covered with a glairy, viscid, and almost insufferably offensive mucus.

The presence of this kind of salivary calculus is attended with very hurtful consequences, not only to the gums, alveolar processes and teeth, but also to the general health. It causes the gums to inflame, swell, suppurate and recede from the teeth—the alveoli to waste, and the teeth to loosen and frequently to drop out. The secretions of the mouth are also vitiated by it, and rendered unfit to be taken into the stomach. Hence, as long as it is permitted to remain on the teeth, neither the skill of the physician, nor the best regulated regimen, though they may afford partial and temporary relief, will fully restore to the system its healthy functions.

As this kind of tartar is seldom if ever met with except in excellent constitutions, the teeth on which it is deposited are generally sound, but they are often caused by the disease which is produced in the gums and alveoli, to loosen and drop out.

The dark brown tartar is not as hard as either of the descriptions of black. It sometimes collects in tolerably large quantities on the lower front teeth, and on the first and second superior molars; it is also often found on all the teeth, though not in as great abundance as on these. It does not adhere with as much tenacity as either of the preceding kinds, and can be more easily detached from them.

It exhales a more fetid odor than the first variety, but is less offensive than the second.

The persons most subject to this kind of tartar, are of mixed temperaments—the sanguinous, however, almost always predominating. They may be denominated sanguiniferous and bilious. Their physical organization, though not the strongest and most perfect, may, nevertheless, be considered very good. But, being more susceptible to morbid impressions, their general health is less uniform, and more liable to impairment than those possessed of the most perfect constitutions.

The effects arising from accumulations of this description of salivary calculus, both local and constitutional, are less hurtful than the variety last noticed, but like that, it causes the gums to inflame, swell, suppurate, and to retire from and expose the necks of the teeth, the alveoli to waste, the teeth to loosen and sometimes to drop out. It also gives rise to a vitiated condition of the fluids of the mouth.

Salivary calculus of a light or pale yellowish brown color, is of a much softer consistence than the darker varieties, and is seldom found upon the teeth, except of persons of bilious temperaments, or those in whom this predominates. It has a rough and for the most part, a dry surface; it is found in large quantities opposite the mouths of the salivary ducts, and sometimes every tooth in the mouth is completely imbedded in it. It contains less of the earthy salts and more of the fibrina and animal fat than any of the foregoing descriptions, and from the quantity of vitiated mucus in and adhering to it, has an exceedingly offensive smell. It is, sometimes, though not always, so soft that it may be crumbled between the thumb and finger.

Inflammation, turgescence and suppuration of the gums, inflammation of the alveolo-dental periosteum, the destruction of the sockets and loss of the teeth, and an altered condition of the fluids of the mouth, are among the local effects produced by the long continued presence of large collections of this variety of tartar. The constitutional effects are not

much less pernicious. Indigestion and general derangement of all the assimilative functions are among the most common. When the deposit is not large, inflammation and sponginess of such parts of the gums as are in immediate contact with it, and fetid breath, are the principal of the unpleasant effects produced by it.

White tartar rarely collects in very large quantities, and though most abundant on the outer surfaces of the first and second superior molars, and the inner surfaces of the lower incisors, it is nevertheless frequently found on all the teeth. Its calcareous ingredients are less abundant than those of any of the preceding descriptions. Fibrina, animal fat, and mucus, constitute by far the larger portion of its substance. It is very soft, seldom exceeding in consistence common cheese curd, to which in appearance it bears considerable resemblance. Although it exerts but little mechanical irritation upon the gums, it keeps up a constant morbid action in them. Its effects, however, upon the teeth, are by far more deleterious than any other description of tartar. It corrodes the enamel, and causes rapid decay of the organs. The fluids of the mouth are also vitiated by it.

It is only upon the teeth of persons of mucous habits, or those who have suffered from diseases of the mucous membranes, or those in whom these tissues have been more or less involved, that this kind of tartar accumulates.

There is one other kind of tartar described by dental writers. It is of a dark green color, and is seen more frequently on the anterior surfaces of the upper teeth occupying the front part of the mouth, than on any of the others. It resembles more that of a stain on the enamel than salivary calculus. Children and young persons are more subject to it than adults, though it is occasionally observed on the teeth of the latter. It is exceedingly acrid, and has the effect of decomposing the enamel; the margins of the gums around the teeth having it on them, are inflamed, and the sanguinous capillaries of their whole substance appear to be distended and more than ordinarily languid.

This kind of discoloration of the enamel is indicative of an irritable condition of the mucous membranes and viscosity of the fluids of the mouth. Sour eructations, vomitings, diarrhea and dysentery are not unfrequent with those whose teeth are thus affected.

For the chemical constituents of salivary calculus, the reader is referred to a subsequent chapter, where, also, the morbid effects produced by its several varieties are treated of more at large.

CHAPTER FIFTH.

PHYSICAL CHARACTERISTICS OF THE FLUIDS OF THE MOUTH.

IN treating upon the physical characteristics of the fluids of the mouth, it will not be necessary to dwell at much length on their effects, when in a morbid condition, on this cavity. Concerning their agency in the production of caries of the teeth, we shall add one or two remarks.

Saliva, in healthy persons having good constitutions, has a light frothy appearance, and but little viscosity. Inflammation of the gums from whatever cause produced, increases its viscosity, and causes it to be less frothy. In a healthy state, it is inodorous, floats upon and mixes readily with water, but when in a viscid or diseased condition, it sinks and mixes with it with difficulty.

Irritation in the mouth, from diseased gums, aphthous ulcers, inflammation of the mucous membrane, the introduction of mercury into the system, or taking any thing pungent into the mouth, increases the flow of this fluid, and causes it to be more viscid than it is in its natural and healthy state.

In treating on the signs of the saliva, Professor Schill says, "The sympathetic affection of the stomach in pregnancy is sometimes accompanied by salivation, which, in this case mostly takes place after conception, and sometimes continues to the time of delivery. It is also observed to occur in weakened digestion, in gastric catarrhs, after the use of emetics, in mania, in what are called abdominal obstructions, in hypochondriasis and hysteria; salivation occurs during the use of mercury or antimony.

"In confluent small-pox, salivation is a favorable sign. If it cease before the ninth day the prognosis is bad. In lingering intermittents, salivation is sometimes critical; more frequently in these affections it precedes the termination in dropsy.

"Diminution of the salivary secretion, and, in consequence of this, dryness of the mouth, is peculiar to the commencement of acute disease, as also to the hectic fevers occasioned by affections of the abdominal organs. If the flow of the saliva stop suddenly, there is reason to apprehend an affection of the brain.

"Thick viscid saliva occurs under the same circumstances as the diminution of the salivary secretion, especially in small-pox, typhus, and in hectic fevers. It is thin in ptyalism. In gastric diseases, where the liver participates, it becomes yellow or green; by the admixture of blood it may assume a reddish color; in pregnant or lying-in women, it is sometimes milky; an icy cold saliva was observed by the author in face-ache.

"Frothy saliva from the mouth is observed in apoplexy, epilepsy, hydrophobia, and in the hysterical paroxysms."*

Dr. Bell, of Philadelphia, in a note to the work from which we have just quoted, says, "acid saliva is regarded by M. Donne, as indicative of gastritis or deranged digestion. Mr. Laycock," he observes, "on the other hand, infers from numerous experiments on hospital patients, that the saliva may be acid, alkaline, or neutral, when the gastric phenomena are the same. In general, Mr. L. remarked, that it was alkaline in the morning and acid in the evening."

We have had occasion to observe, that the acid quality of the saliva was more apparent, and more common in lymphatic, mucous and bilious dispositions, than in sanguinous or in sanguino-serous persons, and that weakened or impaired digestion always had a tendency to increase it.

* *Outlines of Pathological Semeiology*; edition of the Select Medical Library, pp. 173-4.

M. Delabarre says, "when this fluid," (the saliva,) "has remained in the mouth some moments, it there obtains new properties, according to each individual's constitution and the integrity of the mucous membrane, or some of the parts which it covers.

"In subjects who enjoy the best health, whose stomach and lungs are unimpaired, the saliva appears very scarce, but this is because it passes into the stomach almost as soon as it is furnished by the glands that secrete it. It only remains long enough in the mouth to mix with a small quantity of mucus, and absorb a certain portion of atmospheric air, to render it frothy.

"On the other hand, the saliva of an individual whose mucous system furnishes a large quantity of mucus, is stringy and heavy; is but slightly charged with oxygen, contains a great proportion of azote and sulphur, and stains silver."*

Increased redness and irritability of the mucous membrane of the mouth, is an almost invariable accompaniment of general acidity of these fluids. Excoriation and aphthous ulcers, and bleeding of the gums, also, frequently result from this condition of the salivary and mucous secretions of this cavity.

Anorexia, languor, general depression of spirits, headache, diarrhea, and rapid decay of the teeth, are very common among persons habitually subject to great viscosity of the buccal fluids. It is likewise among subjects of this kind, and particularly when the viscosity is so great as to cause clamminess of these secretions, that the green discoloration of the enamel of the teeth is most frequently met with.

CHAPTER SIXTH.

PHYSICAL CHARACTERISTICS OF THE LIPS.

THE indications of the physical characteristics of the lips are more general than local, and the observations of Laforgue and Delabarre on this subject, leave little to be added. We cannot, therefore, do much more than repeat what they have said.

“The lips,” says Delabarre, “present marked differences in different constitutions. They are thick, red, rosy or pale, according to the qualities of the arterial blood that circulates through their arteries.”

Firmness of the lips, and a pale rose color of the mucous membrane that covers them, are, according to Laforgue, indicative of pure blood, and, as a consequence, of a good constitution. Redness of the lips, deeper than that of the pale rose, is also mentioned, as one of the signs of sanguino-serous blood. Soft pale lips are indicative of lymphatico-serous dispositions. In these subjects the lips are almost entirely without color. When there is a sufficiency of blood the lips are firm, though variable in color, according to the predominancy of the red or serous parts of this fluid.

Both hardness and redness of the lips, and all the soft parts of the mouth, are enumerated among the signs of plethora. Softness of the lips, without change of color in their mucous membrane, is spoken of by the last author as indicative of deficiency of blood; and softness and redness of the mucous membrane of the lips are signs that the blood is small in quantity and sanguino-serous.

Serous *anæmia* and pale blood are indicated by want of color and softness of the lips, and general paleness of the mucous membrane of the whole mouth.

"The fluids contained in the vessels, says Laforge in the three foregoing forms of anæmia, "yield to the slightest pressure, and leave nothing between the fingers but the skin and cellular tissue."

In remarking upon the signs of the different qualities of the blood, the above mentioned author asserts that the constitution of children, about the age of six years, cannot, by a universal characteristic, be distinguished, but that the lips, as well as other parts of the mouth, constantly betoken "the quality of the blood and that of the flesh;" and, "consequently, they proclaim health or disease, or the approach of asthenic and adynamic disorders, which the blood either causes or aggravates."

Again, he observes, that the blood of all children is "superabundantly serous," but that it is redder in those of the second constitution than in those of any of the others; and that this is more distinctly indicated by the color of the lips. "This quality of the blood," says he, "is necessary to dispose all the parts to elongate in their growth. When the proportions of the constituent elements of the blood are just, growth is accomplished without disease. If the proportions are otherwise than they should be for the preservation of the health, or if one or more of its elements be altered, health no longer exists, growth is arrested altogether, or is performed irregularly. The nutritive matter is imperfect—assimilation is prevented or impaired. On the other hand, disintegration decomposes the patient; if death does not sooner result, it will consume him by the lesion of some vital organ."*

The changes produced in the color of the blood by organic derangement are at once indicated by the color of the lips.

The accuracy of Laforge's observations on the indications of the physical characteristics of the lips, has been fully confirmed by subsequent writers. Delabarre, in his

* Vide *Seimeologie Buccale et Buccamancie*.

remarks on the semeiology of the mouth, has added nothing to them.

“The secretion of the lips,” says Professor Schill, “has a similar diagnostic and prognostic import to that of the tongue and gums. They become dry in all fevers and in spasmodic paroxysms. A mucous white coating is a sign of irritation or inflammation of the intestinal canal; accordingly, this coating is found in mucous obstructions, in gastric intermittent fever, in mucous fever, and before the gouty paroxysm. A dry brown coating of the lips is a sign of colliquation in consequence of typhus affections; it is accordingly observed in typhus, in putrid fever, in acute exanthema, and inflammations which have become nervous.”*

The appearances of the lips, however, do not present so great a variety as those of other parts of the mouth, for the reason that they are not as subject to local diseases, but their general pathological indications are, perhaps, quite as decided.

* Vide *Pathological Semeiology*, p. 152.

CHAPTER SEVENTH.

PHYSICAL CHARACTERISTICS OF THE TONGUE.

THE appearance of the tongue, both in health and disease, is regarded by physicians as furnishing more correct indications of the state of the constitution and general health, than any of the other parts of the mouth. It is asserted, however, by others, and by those, too, who have the very best opportunities for inspecting the various parts of this cavity, that the lips and gums furnish as marked and reliable indications as the tongue. That the state and quality of the blood can be as readily ascertained by an examination of these, as by that of the tongue, is, we believe, undeniable, but that the pathological condition of the body can, is a question we leave for others to decide.

So far as the quality of the blood and the temperament of the subject are indicated by the color of the tongue, the preceding remarks concerning the lips will be found applicable. The one is as much influenced by them as the other. It will, therefore, be unnecessary to recapitulate what we have before said upon the subject.

The effects produced on the mucous membrane of the tongue, by disease in another part, are said to be analogous to those produced on the general integument. So, also, are the changes of its color, consistence, humidity and temperature similar to those of the skin. We are likewise told that the changes of its coating agree with the analogous changes of the perspiration, and that these phenomena are more decided in acute than in chronic affections.*

*Vide *Professor Schill's Semeiology*.

But the diagnostic and prognostic indications of the tongue vary according to the temperament and constitutional predisposition of the individual. The physician should acquaint himself with its appearances in health, to be able to determine correctly its indications in disease. He should likewise inform himself of the changes produced in its appearance by certain morbid conditions of the body. In some subjects it is always slightly furred, especially near its root, and rather dry; in others it is always clean and humid; in some, again, it is always red, and in others pale.

Professor Schill divides the signs of the tongue into objective and subjective. To the objective, "the changes of size, form, consistence, color, temperature, secretion," and those of its motion belong;" and "to the subjective, the anomalous sensations of taste." We do not know, however, that any advantage can be derived from this classification.

In enumerating the pathognomic signs of the tongue, this author says that hypertrophy, inflammation or congestion, may occasion its enlargement; and that inflammatory swelling of it, when arising from acute diseases, such as "angina, pulmonary inflammation, measles, plague, or variola, yields an unfavorable prognosis. Even non-inflammatory swelling of the tongue, is a dangerous phenomenon in acute diseases, especially cerebral, which are combined with coma. If it be the consequence of mercury, of the abuse of spirituous drinks, of gastric inflammation, of chlorosis, of syphilis, or if it occur in hysteria or epilepsy, the prognosis is not dangerous; but the disease is always the more tedious where the tongue swells than where it does not. It is enlarged, also, by degeneration and cancer."

"Diminution of the size of the tongue takes place where there is considerable emaciation. In this case it continues soft and movable. If in acute states, the tongue becomes small, and is, at the same time, hard, retracted and pointed, the irritation is very great, and the prognosis bad. This sign occurs more especially in typhus, in the oriental cholera, in inflammation of the lungs, and in acute cerebral affec-

tions. In hysteria and epilepsy this phenomenon has no unfavorable import."

Internal maladies, he says, seldom cause the form of the tongue to change, but that the slightest change arising from chronic irritations of the stomach, chronic dyspepsia, and acute exanthems, is enlargement of its papillæ. In cases of protracted dyspepsia, the edges of the tongue sometimes crack, and in paralysis and epilepsy, it becomes elongated.

In acute diseases, a soft tongue is a favorable indication, and flaccidity of it, that of debility.

Humidity of the tongue, he tells us, is a favorable sign, and that dryness of it occurs in acute or violent inflammations and irritations, and more particularly when seated in the intestinal canal, and respiratory organs. "This also happens in diarrhea, typhus, pneumonia, gangrene of the lung, pleuritis, peritonitis, enteritis, catarrhus gastricus, gastritis, inflammation of joints, etc. Among the higher degrees of dryness, he enumerates the rough, the fissured and burnt tongue, as furnishing still more unfavorable indications, informing us at the same time, that if these be not accompanied by thirst, they prognosticate a fatal termination. The abatement and crisis of the disease is indicated by the tongue becoming moist."

Dr. Bell, of Philadelphia, in a note to Professor Schill's observations on the tongue, says, "a rough and dry, and even furred tongue, is seen in some dyspeptic persons, who sleep with the mouth open; and although it indicates an irritation of the digestive organs, it is not of a bad augury." Bilious persons, not unfrequently, though not troubled with any manifest symptoms of gastric or intestinal derangement or any other apparent functional disturbance, have a furred tongue in the morning.

Paleness of the tongue, says Professor Schill, is a sign of a serous condition of the blood, of chlorosis, of great loss of blood, of chronic disorders, of sinking of the strength in acute maladies, assuming a "nervous form, as typhus and

scarlatina maligna. It is also found," says he, "in enteritis and dysentery, when but little fever is present." He infers from this, that paleness of the tongue is caused by the "drawing of the fluids downwards," but it is often observed in persons who enjoy tolerably good health. Lymphatic dispositions, as has been before remarked, are peculiarly subject to it.

Again, he observes, that a very red tongue is indicative of "violent inflammation, mostly of the intestinal canal, but also of the lungs, of the pharynx and of acute exanthems." He regards the prognosis as bad, when a furred tongue "in acute diseases of the intestinal canal becomes clean and very red," if the change is not accompanied with the return of the patient's strength. "But," he continues, "if the debility is not considerable, and the tongue becomes clean and very red, whilst other febrile symptoms continue, a new inflammation may be expected." But even in affections like these, the redness of the tongue is always more considerable in sanguinous, than in lymphatic or lymphatico-serous subjects, so that in forming a prognosis from this sign, the temperament of the individual should never be overlooked.

Proceeding with the description of the signs of this organ, he says, "the tongue becomes a blackish-red and bluish-red in all serious disturbances of the circulation and respiration, as also in severe diseases of the lungs and heart, as catarrhs, suffocations, asthma, extensive inflammations of the lungs, carditis, Asiatic cholera, plague, confluent small-pox, and putrid fevers. It becomes black and livid in cases of vitiation of the blood, more especially in scurvy, at the setting in of gangrene, and in phthisis, when death is near at hand."

Among the diseases mentioned as giving rise to an increase of the temperature of the tongue, are glossitis, violent internal inflammation and typhus fever; and coldness of this organ is observed to take place in Asiatic cholera, and at the approach of death.

The signs from the secretion of the tongue are thus enumerated. A clean and moist tongue are favorable indications, but a clean, dry and red tongue, as are seen in slow nervous fevers, acute exanthems and plague, are bad auguries. A furred or coated tongue is said to occur chiefly in intestinal disorders, diseases of the lungs, skin, and in rheumatic affections. The coating is said to vary in "color, thickness, adherence, and extent," and different kinds of secretion from the mucous membrane of this organ are mentioned as occurring in different diseases, and it should have been added in the same disease in different temperaments.

After describing the various kinds of coating on the tongue, together with their respective indications, which it is not necessary here to enumerate, the occurrence of false membranes and pustules, resulting from peculiar forms of mucous secretion, are next mentioned. The former show themselves either as small white points, or large portions, and sometimes they are said to envelop the whole tongue. The color is "sometimes white, sometimes yellow and sometimes red," and the greater the surface covered by them, the more unfavorable is the prognosis regarded. "Pustules on the tongue," says our author, "are sometimes idiopathic, but in most cases symptomatic. They are either distinct or confluent; the confluent are the worst. Those which are hardish and dry, and also those which are blue, and those of a blackish appearance, which sometimes occur in acute diseases, are of an unfavorable import." On the other hand, those which have a whitish, soft, moist, and semi-transparent appearance, are less unfavorable, and when the eruption or aphthæ is repeated, it portends a longer continuance of the malady. To the following diseases, they are mentioned as being frequent accompaniments; namely, gastritis, catarrhs, enteritis, metritis, dysentery, cholera infantum, peritonitis, intermittent and typhus fevers, pleuritis, pneumonia, and the third stage of pulmonary consumption. Their prognosis is said to be favorable, when

“they appear with critical discharges after the seventh day,” and unfavorable, when they occur as a consequence of a general sinking of the physical powers of the body.*

But it is unnecessary to enumerate all of the pathognomic indications of the various morbid phenomena described by semeiologists; we have noticed more of them than was our intention to have done. We shall, therefore, conclude the present inquiry, by simply observing, that the indications furnished by the physical characteristics, of not only the tongue, but those, also, of the teeth, the gums, salivary calculus, the lips and fluids of the mouth, are, as we have endeavored to show, essential to the successful exercise of the duties both of the dental and medical practitioner.

* Vide *Professor Schill's Semeiology*.

PART THIRD.

DISEASES OF THE TEETH AND THEIR TREATMENT.

DISLOCATION OF THE LOWER JAW.

PART THIRD.

DISEASES OF THE TEETH.

THE doctrine that the diseases of the teeth are the same as those which attack other osseous structures of the body, as promulgated by Fox, and, subsequently, advocated by Bell, and other European writers, is now almost universally conceded to be incorrect. With the exception of exostosis and necrosis, the pathological conditions of these organs do not bear the slightest analogy to those of other bones. They are not produced by the same causes, nor can they be cured by the same remedies. In the treatment of those of the former, art must do all; in those of the latter, the recuperative powers of the economy are the resources principally to be relied on.

The teeth are more liable to be attacked by caries than any other disease, and this, therefore, will first claim our attention.

CHAPTER FIRST.

CARIES OF THE TEETH.

CARIES of a tooth is the chemical decomposition of the earthy salts of the affected part, sometimes, but not always, accompanied by the disorganization of the animal framework of this portion of the organ. There is no affection to which these organs are liable, more frequent in its occurrence, or fatal in its tendency, than this. It is often so insidious in its attacks, and rapid in its progress, that every tooth in the mouth is involved in irreparable ruin, before its existence is scarcely suspected.

Its presence is usually first indicated by an opaque or dark spot on the enamel; and, if this be removed, the subjacent dentine will exhibit a black, dark-brown or whitish appearance. It usually commences on the outer surface of the dentine of the crown, beneath the enamel, at some point where it is imperfect or has been fractured or otherwise injured; from thence it proceeds towards the centre of the tooth, increasing in circumference, until it reaches the pulp cavity.

If the diseased part is of a soft and humid character, the enamel, after a time, usually breaks in, disclosing the ravages the disease has made on the subjacent dentine. But this does not always happen; the form of the tooth sometimes remains nearly perfect, until its whole interior structure is destroyed.

There is no portion of the crown or neck of a tooth exempt from the disease; yet, some parts are more liable to be first attacked than others; as, for example, the depressions in the grinding surfaces of the molars and bicuspid,

the approximal surfaces of all the teeth—the posterior or palatine surfaces of the lateral incisors; and, in short, wherever an imperfection of the enamel exists.

The enamel is much harder than the dentine, and is by far less easily acted on by the causes that produce the disease. It is sometimes, however, first attacked, and when this happens, the disease develops itself more frequently on the labial, or buccal surface near the gum, than in any other locality—often commencing at a single point, and at other times at a number of points. When the enamel is first attacked, it is usually called erosion; but as this tissue does not contain so much animal matter as the subjacent dentine, the diseased part is often washed away by the saliva of the mouth, while in the dentinal part of the tooth, it, in most instances, remains, and may be removed in distinct laminae, after the earthy salts have been decomposed.

In very hard teeth, the decayed part is of a firmer consistence, and of a darker color, than in soft teeth. Sometimes it is black; at other times of a dark or light brown; and at other times again, it is nearly white. As a general rule, the softer the tooth, the lighter, softer and more humid the caries. The color of the decayed part, however, may be, and doubtless is, in some cases, influenced by other circumstances—perhaps by some peculiar modification of the agents concerned in the production of the disease.

The disease then, not being the result of any vital action, the applicability of the term caries may be questioned; but, as it has been very generally sanctioned, and as we know of no better name, we shall continue its use. Mr. Bell has substituted the term gangrene, under the belief that it conveys a more correct idea of the true nature of the affection. The applicability of a term, almost synonymous with this, is also suggested by Mr. Hunter; who, in speaking of the affection, says, it “appears to deserve the name of mortification.” Mr. Fox, too, treats of the decay of the teeth, as a disorder which terminates in mortification, but he designates it by the name of caries, and we prefer this term, in-

asmuch as that of gangrene or mortification may be applied to another condition of the teeth ; namely, necrosis, with as much propriety as to the one now under consideration. Moreover, the term gangrene, or mortification, is usually used to signify the death of a soft part, and not a diseased condition of a bony tissue.

Commencing externally beneath the enamel, the disease proceeds, as we have before stated, towards the centre of the tooth, destroying layer after layer, until it reaches the lining membrane, leaving each outer stratum softer, and of a darker color than the subjacent one.

The appellations, *deep seated*, *superficial*, *external* and *internal*, *simple* and *complicated*, have been applied to the disease. These distinctions are unnecessary, since they only designate the different stages of the same affection. By complicated decay, is meant caries which has penetrated to the pulp cavity of the tooth, accompanied by inflammation and suppuration of the lining membrane, and the death of the organ. The lining membrane, however, is not always inflamed by exposure, nor suppurated by inflammation.

Equally unnecessary is the classification adopted by M. Duval, to designate the differences of color and consistence exhibited by the decayed part. He enumerates seven varieties or species, which are as follows: *calcareous*, *peeling*, *perforating*, *black*, *deruptive*, *stationary* and *wasting*.

The *first*, he employs to denote that affection of the teeth characterized by the appearance of a white opaque spot on the enamel, whereby it is rendered brittle, and often caused to break. The *second*, if not identical with, is at least analogous to the first—the difference consisting only in the color of the enamel. The *third*, from a defect in almost every part of the enamel covering the crowns of the teeth, attacks the molars and sometimes the bicuspid, at a number of points simultaneously, causing speedy destruction. The *fourth*, he describes as not occurring until from the fifteenth to the thirtieth year, and as being principally con-

fined to persons of consumptive habits, and those disposed to rachitis. The color of the decayed part of a tooth in individuals having such morbid proclivity, is sometimes black, but more frequently white. Black caries, as it is called, is oftener met with in the teeth of persons of good constitutions, and in hard rather than soft teeth.

The *fifth species*, or deruptive, he represents as that which attacks the front teeth of individuals of consumptive habits near the necks of the organs, extending downwards towards their roots, and forming a brownish semicircular groove. The *sixth*, is that description, which, after having penetrated a certain distance into the substance of the tooth, becomes stationary. The *seventh* and last species, is characterized by the gradual wasting of the grinding surfaces of the molars, dipping down in some places to a considerable depth, and leaving a smooth polished surface of a brown or yellowish color.

Finally, the roots of the teeth frequently remain firm in their sockets for years after the crowns and necks have been destroyed, showing that they are less liable to decay than the crowns; but nature, after the destruction of the last, as if conscious that the former are of no further use, exerts herself to expel them from the system, which is effected by the gradual wasting and filling up of their sockets. It often happens, that after this operation of the economy has been accomplished, they are retained in the mouth for months, and oftentimes for years, by their periosteal connections with the gums. But this effort of nature, is confined more to the back than to the front teeth, for it often happens that the last remain for a great number of years, and sometimes seemingly without much injury to the parts within which they are contained, after the destruction of the crowns.

DIFFERENCES IN THE LIABILITY OF DIFFERENT TEETH TO DECAY.

Having explained at some length, in a preceding part of this work, the manner in which the physical condition of

the teeth is influenced, it will not be necessary now to dwell upon this portion of our subject. It will only be requisite to state, therefore, that teeth which are well formed, well arranged and of a firm texture, seldom decay, and when they are attacked, the progress of the disease is not rapid; whereas, those that are imperfect in their formation, and of a soft texture, are more susceptible to the action of the causes which produce it, and when assailed, if the progress of the affection is not arrested by art, they usually fall speedy victims to its ravages. So just in proportion as the dentinal structure of the teeth is hard or soft, the shape of the organs perfect or imperfect, their arrangement regular or irregular, is their liability to caries diminished or increased.

The density, shape and arrangement of the teeth, are influenced by the state of the general health, and that of the mouth, at the time of their dentinification. If, at this period, all the functions of the body are healthily performed, these organs will be compact in their structure, perfect in their shape, and usually regular in their arrangement.

That the teeth should be thus influenced, will not appear strange, when we consider, that "there exists," as Riche-rand remarks, "amongst all the parts of the living body, intimate relations, all of which correspond to each other, and carry on a reciprocal intercourse of sensations and affections." Hence, if there is a morbid action in one part, other parts sympathize with it, and, as if sensible of the mutual dependence existing between them, rally all their energies to rescue their neighbor from the power of disease.

Increased action in one portion of the system, is generally followed by diminished action in some other part; thus for example, gastritis is usually produced by constipation of the bowels: puerperal fever, by diminished action in the heart, and an increased action in the uterus, etc. Hence, we may conclude, that if the body, at an early age, be morbidly excited, its functions will be languidly performed—the process

of assimilation checked—the regular and healthy supply of earthy matter interrupted—and that, consequently, the teeth which are then formed, will be defective. Other parts of the body, in which constant changes are going on, if thus affected at these early periods, may afterwards recover their healthful vigor; but if the teeth are badly formed, they must ever, because of their low degree of organization, continue so, and, consequently, be more liable to decay than when dentinified under other and more favorable circumstances.

“That the teeth acquire this disposition,” says Mr. Fox, “to decay, from some want of healthy action during their formation, seems to be proved by common observation, that they become decayed in pairs; that is, those which are formed at the same time, being in a similar state of imperfection, have not the power to resist the causes of the disease, and, therefore, nearly about the same period of time exhibit signs of decay; while those which have been formed at another time, when a more healthy action has existed, have remained perfectly sound to the end of life.”

Most writers are of the opinion, that the power of the teeth to resist the various causes of decay is sometimes weakened by a change brought about in their physical condition through the agency of certain remote causes, such as the profuse administration of mercury, the existence of fevers, and all severe constitutional disorders.

Mr. Fox says, “That he has had occasion to observe, that great changes take place in the economy of the teeth in consequence of continued fever; and that the decay of the teeth is often the consequence of certain states of the constitution.”

Mr. Bell remarks: “That amongst the remote causes, (of decay,) are those which produce a deleterious change in the constitution of the teeth, subsequent to their formation; one of the most extensive, in its effects, is the use of mercury. To the profuse administration of this remedy in tropical diseases, we may, we think, in a great measure, attribute

the injury which a residence in hot climates so frequently inflicts on the teeth."

Severe constitutional disorders, and the administration of certain kinds of medicine, do not, as Mr. Fox and Mr. Bell suppose, act directly upon the teeth, by altering their physical condition and thus rendering them more susceptible to the action of corrosive agents; but they are indirectly affected in proportion as the secretions of the mouth are vitiated and their corrosive properties increased.

The following considerations establish, to our mind, the truth of what we have just stated. Artificial teeth of bone or ivory, which can undergo no such changes as those mentioned by Mr. Bell, decay more rapidly after the profuse administration of any medicine, or during the existence of any disease that tends to vitiate the secretions of the mouth, than at other times. Furthermore, teeth of so dense a texture, as to be capable of resisting the action of the acidulated buccal fluids—though just as liable as those of a spongy texture, to any disease communicated from the general system, by changing their internal economy, are not affected by constitutional disease.

The following is the result of our own observations: The gums and alveolar processes are sometimes destroyed by the use of mercury, so that all the teeth loosen and drop out, without being affected by caries. The teeth of persons, in whom a mercurial diathesis has been for a long time kept up, or who have been for years suffering from dyspepsia, phthisis, fevers, or other severe constitutional disorders, often continue perfectly sound, while other teeth, under similar circumstances, frequently decay. Now, all this goes to prove, not that changes are effected in the structural condition of the teeth, whereby their predisposition to decay is increased, but that there are differences in the capabilities of different teeth to resist the action of the acrid secretions of the mouth, caused by the affections just enumerated.

The predisposition of teeth to decay, may, however, be

increased by improper dental operations, as injudicious filing, careless plugging, etc.

The author is aware that he differs from some on this point, as well as from received popular opinion. The views which he has here presented, are not the result of mere closet reflections partially matured, but of long and attentive observation. He has noted the effects of mercury, and of other medicines, as well as of constitutional diseases of the severest and most protracted kinds, and he has always observed, that it was only as they impaired the healthy qualities of the fluids of the mouth, that they affected the teeth. In fact, the density of these organs, their exposed situation, their functions, all would seem to indicate, that such changes as take place in other parts of the body, are not only unnecessary, but many of them even impossible.

Dr. Good says, "That caries of the teeth does not appear to be a disease of any particular age or temperament, or state of health." It is true it is not a disease of any particular state of health, farther than that certain constitutional affections exert a deleterious influence upon the secretions of the mouth, and thus become indirect causes of decay of these organs. That it is not a disease of any particular age, seems to contradict common experience, for it *comparatively* seldom happens that caries appears after the age of forty. The reason of which is obvious. Teeth of a loose texture, or otherwise imperfect, cannot resist the action of the causes of decay, to which all teeth are more or less exposed to this period of life, while those which from their greater density remain unaffected thus long, are generally enabled, by the increased solidity they gradually acquire, to resist them through life. Teeth, however, do sometimes, though rarely, decay at fifty, or even at a later period. But caries of the teeth, generally, may be said to be confined to youth and middle age.

The formation, arrangement and physical condition of the teeth, are sometimes influenced by hereditary diatheses of the general system, or of the parts concerned in their

production, and that a morbid condition of the system, either on the part of the father or mother, often predisposes their progeny to like affections, is an axiom fully recognized in pathology, and a fact of which we have many fearful proofs.

Mr. Bell, in treating of what he calls the hereditary predisposition of the teeth to decay, remarks: "That it often happens that this tendency exists in either the whole or a great part of a family of children, where one of the parents had been similarly affected; and this is true to so great an extent, that we have commonly seen the same tooth, and even the same part of a tooth, affected in several individuals of the family, and at about the same age. In other instances, where there are many children, amongst whom there exists a distinct division into two portions, some resembling the father, and some the mother, in features and constitution, we observe corresponding differences in the teeth, both as it regards their form and texture, and their tendency to decay."

That there is an hereditary tendency in the teeth to decay, cannot, we think, be denied. But we believe it to be the result of the transmission of a similarity of action in the parts concerned in the production of these organs, so that the teeth of the child are, in form and structure, like those of the parent whom it most resembles, and from whom it has inherited the diathesis. The teeth of the child being shaped like those of the parent, possess a like degree of density, and, in most instances, similarly arranged, are equally liable to disease, and when exposed to the action of the same causes, are affected in like manner, and, usually, at about the same period of life. Such being the fact, is it unreasonable to conclude, that judicious early attention may so influence the formation and arrangement of the teeth, that their liability to disease may be diminished? It is, then, to the differences in the physical condition and manner of arrangement of these organs, in different individuals and in the same mouth, that the differences in their liability to decay is attributable.

CAUSES OF CARIES.

Caries of the teeth has been attributed to a great variety of causes, and to notice, in detail, the various opinions advanced by American, English, French and German writers upon this subject, would be both inconsistent with the plan of an elementary treatise like this, and unprofitable to the reader; we shall, therefore, content ourself with a very brief exposition of the views of a few of the most prominent writers, and if, in doing this, we shall have occasion to differ from any, we trust we shall be able to give satisfactory reasons for so doing.

Fauchard, Anzebè, Bourdet, Lecluse, Jourdain, and most of the French writers of the eighteenth century on the diseases of the teeth, as well as nearly all of the more modern French authors, though their views with regard to the causes of dental caries are exceedingly vague and confused, express the belief that the disease is, for the most part, the result of the action of chemical agents; such, for example, as vitiated saliva, the putrescent remains of particles of food lodged between the teeth, or in their interstices, acids, and a corrupted state of the fluids conveyed to these organs for their nourishment. They also mention certain states of the general health, mechanical injuries, sudden transitions of temperature, etc., as being conducive to the disease. A similar explanation, too, of the cause is given by Salmon, the author of a *Compendium of Surgery*, published in London, in 1644.

The foregoing is a general summary of the views entertained by most of the older writers with regard to the cause of the disease under consideration, and, if they are not strictly correct, we think we shall presently be able to show that they are not altogether erroneous.

In the English school of dental surgery, since the time of the publication of Mr. Fox's celebrated treatise on the *Natural History and Diseases of the Teeth*, and until quite re-

cently, inflammation of the dentine has been regarded as the proximate or immediate cause of the disease.

Having discovered an identity of structure between the teeth and the bones of the body, this author immediately concluded that the diseases of the one were identical with those of the other. This inference, it must be confessed, to one who has not made the diseases of the former a subject of close and critical investigation, would seem to be irresistible. But it is evidently incorrect, so far, at least, as most of the diseases of the teeth are concerned. By instituting a comparison between caries of the teeth and that of bone, it will at once be perceived that there is not the slightest analogy between the disease, as it occurs in the one, and shows itself in the other. In the former, it consists simply in a decomposition of the earthy salts of the organs, whereas, in the latter, it is analogous to ulceration in soft parts, and constantly discharges fetid sanies, and throws out granulations of fungous flesh. These are phenomena which dental caries never presents, and they establish a wide difference of character between it and the disease as occurring in the true osseous structures of the body.

But the promulgation of the doctrine of the vascularity of the teeth, not only led to the belief that caries of these organs was identical with caries of bones, but it soon gave rise to the supposition, that, inasmuch as inflammation was the cause which determined it in the latter, it also produced it in the former.* Among the ablest advocates of this theory is Mr. Thomas Bell, but, notwithstanding the support which it has received from his pen, it is opposed by facts which prove it, most conclusively, to be erroneous.

If inflammation of the dentinal structure of the teeth

*The doctrine of the vascularity of the teeth, as maintained by Fox, was the origin of the theory in England, that caries of these organs resulted from inflammation of their dentinal structure, but the doctrine had been advanced at a much earlier period in France. The celebrated French surgeon, Ambrose Paré, in treating on tooth-ache, says, "these organs, after the manner of other bones, suffer inflammation," and "quickly suppurate, become rotten," etc., book xvii, chap. xxv, page 387; edition, 1579.

were the cause of caries, the disease would be as likely to develop itself in one part of a tooth as another. The root, the interior of the crown between the pulp-cavity and the enamel, would as frequently be the part first attacked as the external surface. Now what are the facts in relation to this matter? Does caries ever commence on the root of a tooth, or between the pulp-cavity and the periphery of the dentine? Most assuredly not.

Again, among the causes which would be most likely to excite inflammation in these organs, are many of the operations performed for arresting the progress of the disease. For example, it is well known that filing and plugging, two of the most valuable operations in dental surgery, augment, for a time at least, the sensibility of the teeth, and increase their susceptibility to the action of heat and cold—agents regarded as among the most frequent and powerful of the exciting causes of inflammation. Now, if caries of the teeth were the result of inflammation, these operations, instead of arresting the progress of the disease, would cause a recurrence of it, and hasten the destruction of those upon which they had been performed.

Inflammation of the lining membrane of a tooth, may end in suppuration, but we cannot believe that inflammation of its dentinal structure alone, causes a decomposition of any portion of its substance. For were such a change produced by any vital action, the part deprived of vitality, would be exfoliated, and its loss repaired by the formation of new dentine, which never happens; hence, we are led to conclude that the vital powers of the teeth are too weak to set up an action capable of effecting the decomposition, exfoliation, or restoration of any portion of their substance. Were their living powers more active, it is probable their diseases would be more analogous to those of bones.

If inflammation of the dentine, then, is not the cause of the affection, how is the disease produced? This question can only be answered in one way. It is the result of the

action of external chemical agents, and this explanation of the cause is not based upon mere hypothesis. It is supported by facts that cannot be successfully controverted. It is well known, that the fluids of the mouth, especially the mucous, when in a vitiated condition, are capable of decomposing the enamel of the teeth when not possessed of more than ordinary density. The truth of this assertion is demonstrated by the fact that dead teeth, and the crowns of human teeth, or those of animals, when employed as substitutes for the loss of the natural organs, are as liable to decay as living teeth, and the decayed part in the one, exhibits nearly the same characteristics as in the other. The same is true, too, with regard to all artificial teeth constructed from bone of any sort, or ivory. Now, if the disease was dependent upon any vital operation, neither dead teeth nor such dental substitutes as we have mentioned, would ever decay. But inasmuch as they do, is it not reasonable to suppose that the cause which produces it in the one case is capable of producing it in the other?

Inflammation may influence the susceptibility of a tooth to the action of the causes which produce decay, and even the appearance of the decayed part, but it is not the immediate cause of the disease.

But it may be asked, if caries be produced by the action of external corrosive agents, how is it that the disease sometimes commences within the dentinal structure of a tooth, and makes considerable progress there, before any indications of its existence are observed externally? We answer, that it never does commence there; its attacks, as we have before remarked, are always upon the external surface, sometimes upon the enamel, but most frequently upon the dentine beneath the indentations in the grinding surfaces of the bicuspid and molars, and in the approximal sides of the teeth, where this outer covering is frequently so fractured by the pressure of the organs against each other, that the secretions of the mouth find ready access to the subjacent dentinal tissue. Decay may be gradually going on here

for months or years without any manifest signs of its existence: and the commencement of the disease in these places has led many to suppose that it had its origin within the dentinal structure.

A thorough investigation of this subject, ought to convince any one, that caries always commences externally. If it commenced in the interior or within the dentinal substance, as is asserted by some English writers, "the sphere of usefulness," as is very justly remarked by Dr. Fitch, "on the part of the surgeon dentist," would be, "to say the least of it, extremely limited. For, if their observations," alluding to those of Hunter, Fox, Koecker and other European writers, "are true, this disease, in its commencement, in one-half of the cases, is entirely out of the reach of medical aid." Dr. F., however, is of the opinion that it does sometimes commence within the substance of the tooth.

But a still more absurd and ridiculous theory in regard to the cause of the disease is advanced by Mr. Charles Bew. He attributes it to the arrest of the circulation in the organs, "by the lateral pressure of the teeth against each other."

The exposure of the teeth, too, to sudden changes of temperature, as from heat to cold, or cold to heat, has been regarded almost from time immemorial as the cause of their decay, but no explanation of the manner by which these agents produced the disease was attempted, until the promulgation of the doctrine that it was the result of inflammation, then they were numbered among the *exciting causes*. The popular belief that cold is a cause of dental caries, is traced back to Hippocrates, who, in mentioning the parts of the body injuriously affected by it, includes the teeth.*

M. Ribe endeavors to prove that hot food is a cause of caries, from the fact, that "man is the only animal ac-

* Frigidum inimicum ossibus, dentibus, nervis, cerebro, spinali medullæ: calidum varo utile. *Aph. sec. v.*—par. 18.

customed to hot food, and almost the only animal affected with carious teeth." Had this writer instituted a comparison between the teeth of man and of brutes, and between the solvent agents to which they are respectively exposed, he might, doubtless, have traced the decay of the human teeth to its proper cause.

"The Indians of North America," says M. Tillaeus, "knew nothing of the inconvenience of carious teeth and debilitated stomachs, until after the introduction of tea amongst them." From this, one might suppose that tea caused the teeth to decay, and that dyspepsia was mainly attributable to its use.

The decay of the teeth of these people, since the introduction of tea amongst them, may, however, be more plausibly accounted for. The susceptibility of these organs to the action of such causes as produce the disease, have been greatly increased by the impaired state of their general constitutional health, occasioned, since this time, by the use of spirituous liquors, and the luxuries common to civilized life, in which they have indulged.

Particular sorts of diet, too, such for example, as animal food, are said to exercise an unhealthy influence upon the teeth. In proof of the assertion, it is stated, that Indian nations, who live principally upon vegetables, scarcely ever have a tooth to decay. But the same may also be said of those nations who subsist chiefly on animal diet, and who enjoy an equal degree of constitutional health. Savage and barbarous people usually have better teeth than those of civilized nations, probably for the reason that their systems are not enervated by luxurious living. So far as diet is capable of effecting the health of the body, it may be considered as an indirect cause of caries; for the health of the child is not always dependent on the health of the parent, and to the absence of disease in the general system during childhood, the period when the teeth of second dentition are being formed, the soundness of the teeth of savages is attributable

It is absurd to suppose that caries of the teeth is attributable to the use of animal food. It is incapable, even in a putrid state, of exerting any hurtful action on them. The fibres of animal matter may be retained between the teeth longer than particles of vegetable substance, and by retaining the secretions of the mouth until they become vitiated, contribute indirectly to caries of these organs.

Those parts of the teeth which are covered with thick smooth enamel, are rarely, in the first instance, attacked by caries. But the chemical agents concerned in the production of the disease may find access to the dentine through a fracture or imperfection of the enamel scarcely perceptible to the naked eye, and hence, the disease is sometimes developed in a part not usually attacked by it.

Mr. Tomes believes that caries of a tooth is always preceded by loss of vitality in the affected part, and that it is not until this takes place, that the chemical agents, upon the action of which the structural alteration is produced, are capable of affecting the solid tissues of these organs, but that this opinion is erroneous is proven by the fact, that the animal frame-work of the affected part, after the complete decomposition of the earthy salts, is often so exceedingly sensitive, that the slightest touch of an instrument is productive of severe pain, thus demonstrating conclusively the existence of remaining vitality.*

The opinion of Mr. Lintott with regard to the manner in which caries is produced, is founded upon the endosmotic phenomena which he thinks takes place in the structure of a tooth. That endosmosis may take place in the outer part of a tooth is possible, and if it does, the secretions of the mouth, if at all acidulated, would be likely to decompose the calcareous molecules with which they are brought in contact during their imbibition. But whether such action takes place or not, the structural alteration, beyond doubt, is produced by chemical agents.

* See *Tomes' Lectures on Dental Physiology and Surgery*.

The existence of an acid in the mouth, capable of decomposing the teeth, is conclusively proven by Dr. S. K. Mitchell, in a letter addressed by him to T. C. Hope, M. D., of Edinburg, dated October 10th, 1796, and the fact may be demonstrated by a very simple experiment, which consists in moistening a piece of blue paper, dyed with turnsole, with the fluids of this cavity, obtained from between the teeth, where they have been retained until they have become vitiated. If this be done, the paper will be turned red. If, then, these fluids, when in a vitiated condition, are possessed of acid properties, they must necessarily exert a deleterious action upon the teeth, by decomposing and breaking down their calcareous molecules, or, in other words, causing their decay.

The acid detected by Dr. Mitchell was the septic, (nitrous,) but the acetic, lactic, oxalic, muriatic and uric have been detected in the saliva, in certain states of the general health. Donne, who has analysed the fluids of the mouth with great care, says, the saliva, "in its normal state," is alkaline, but that "the secretions of the mucous membrane of the mouth are acid."*

It is highly probable, therefore, that the acids which have been detected in the first of these fluids, may have been principally derived from the latter. Acidity of the saliva may, however, occur in certain morbid conditions of the general system. Donne says, he has observed it in patients affected "with gastritis," "and in children with aphthæ." It is to the action of these acids upon those parts of the teeth, where they are long retained, that caries is principally attributable.

The doctrine that the decay of the teeth is the result of the action of external corrosive agents, was first distinctly promulgated to the dental profession of the United States, about the year 1821, by Drs. L. S. and Eleazar Parmly; and these agents may consist of menstrua, formed by the

* *Course de Microscope*, p. 209.

decomposition or acetous fermentation of the remains of certain aliments, lodged in the interstices of the teeth, or of the fluids of the mouth, especially the mucous, in a vitiated or acidulated condition, or of acids administered during sickness, or used as condiments. According to the tables of elective attraction, there are but four acids, namely, the oxalic, sulphuric, tartaric and succinic, which precede the phosphoric in their affinity for lime. It may hence be argued, that none of the other acids are capable of decomposing the teeth, or of affecting them in any other way prejudicially, but daily observation proves the erroneousness of this conclusion. It has been shown by experiment that all the acids, both vegetable and mineral, act more or less readily upon these organs.* But we are disposed to believe

* The following experiments made by Dr. A. Westcott, in 1843, assisted by Mr. Dalrymple, were repeated some years later, before the class of the Baltimore Dental College.

"1st. Both vegetable and mineral acids act readily upon the bone and enamel of the teeth.

"2d. Alkalies do not act upon the enamel of the teeth; the caustic potash will readily destroy the bone by uniting with its animal matter.

"3d. Salts whose acids have a stronger affinity for the lime of the tooth, than for the basis with which they are combined, are decomposed, the acids acting upon the teeth.

"4th. Vegetable substances have no effect upon the teeth till after fermentation takes place, but all of them, capable of acetic fermentation, act readily after this acid is formed.

"5th. Animal substances, even while in a state of confined putrefaction, act very tardily, if at all, upon either the bone or enamel. On examining the teeth subjected to such influence, the twentieth day of the experiment, no visible phenomena were presented, except a slight deposit upon the surface, of a greenish slimy matter, somewhat resembling the green tartar often found upon teeth in the mouth.

"To give a more definite idea of the deleterious agents to which the teeth are exposed, and their consequent liability to be affected by them, we will notice the effect produced by a few of the individual substances, which are more or less liable to be brought in contact with the teeth.

"Acetic and citric acids so corroded the enamel in forty-eight hours, that much of it was easily removed with the finger nail.

"Acetic acid or common vinegar, is not only in common use as a condiment, but is formed in the mouth whenever substances, liable to fermentation, are suffered to remain about the teeth for any considerable length of time.

"Citric acid, or lemon juice, though less frequently brought in contact with the teeth, acts upon them still more readily.

that caries of the teeth results more frequently from the action of some acid contained in the mucous fluids of the mouth, than from that of acid medicines or condiments, or even from such acids as may be generated by the acetous fermentation of particles of certain kinds of food lodged between the teeth. The author is of the opinion, therefore, that if all the functional operations of the body were always healthily performed, caries of the teeth would seldom occur, for, in this case, the alkalinity of the saliva would be sufficient to neutralize the acidity of the mucous fluids of the buccal cavity, as well as any other acids generated in the mouth.

The foregoing theory of the cause of dental caries, explains the *rationale* of the treatment at present adopted for arresting its progress. By the removal of the decomposed part and filling the cavity with an indestructible material, the contact of those agents, upon the chemical action of which the disease depends, is prevented, and the further progress of the decay arrested.

Among the indirect causes of caries, the following may be enumerated: depositions of tartar upon the teeth, a febrile or irritable state of the body, a mercurial diathesis of the general system, artificial teeth improperly inserted, or of bad materials; roots of teeth; irregularity in the arrangement of the teeth; too great pressure of the teeth against each other, and, in short, everything that is pro-

“Malic acid, or the acid of apples, in its concentrated state, also acts promptly upon the teeth.

“Muriatic, sulphuric and nitric acids, though largely diluted, soon decompose the teeth—these are in common use as tonics.

“Sulphuric and nitric ethers have a similar deleterious effect, as also spirits of nitre—these are common diffusible stimulants in sickness.

“The acids of some of the salts also corrode the teeth.

“Super-tartrate of potash, as an example, destroyed the enamel very readily. This article is frequently used to form an acidulated beverage.

“Raisins so corroded the enamel in twenty-four hours, that its surface presented the appearance and was of the consistency of chalk.

“Sugar had no effect till after acetous acid was formed, but then the effect was the same as from this acid when directly applied.”

ductive of irritation to the alveolo-dental membrane, or gums.

The doctrine we have here advocated, is one which, we confess, we were for a long time unwilling to believe, because it was opposed to all our earlier preconceived notions upon the subject; but long and attentive observation has forced us to acknowledge its truth.

It will be perceived from the foregoing exposition of the causes of dental caries, that three distinct theories have been advanced upon the subject, namely: 1. The *vital*, as advocated by Paré, Fox, Bell, and some others. 2. The *chemical*, as maintained by nearly all French authors, by Salmon, Drs. L. S. and E. Parmly, and by almost all late writers. 3. The *chemico-vital*, of Tomes. We might also add the *endosmotic* theory of Lintott, which, in fact, is nothing more than an explanation of the supposed manner in which chemical agents are brought in more direct contact with the earthy salts of a tooth.

PREVENTION OF CARIES.

It is an old adage, no less true than trite, that "an ounce of prevention is better than a pound of cure," and in the present instance it may be applied with its full force; and were more attention paid to the practical instruction thus conveyed, many of the diseases of the teeth might be avoided.

Most of the remarks that might be made on this subject have been anticipated; consequently, it will only be necessary to observe, that if the teeth are well formed, and well arranged, all that will be required, will be to keep them clean; and if any irregularity occurs, it should be remedied by the means before described.

For cleansing the teeth, the regular and frequent use of a brush and waxed floss-silk, will, in most cases, be sufficient. The enamel should be kept free from all stains and discolorations, by the employment, if necessary, once a day,

of a dentifrice, or what is still better, an argillaceous tooth-polisher. If a powder be preferred, either of the following may be used.

℞ Creta prep. ℥ iv, pul. orris root ℥ iv, pul. cinnamon ℥ ss, sup. carb. soda ℥ ss, sach. alb. ℥ i, ol. lemon gtt. 15, ol. rose gtt. 2, Misce. ℞ Cret. prep. ℥ ii, pul. orris root ℥ ii, prep. pumice stone ℥ i—Misce.

These should be reduced to an impalpable powder, and passed through a sieve, previously to being used.

The importance of keeping the teeth clean, cannot be too strongly impressed upon the mind of every individual. Proper attention to the cleanliness of these organs, contributes more to their health and preservation than is generally supposed. Against caries it is a most powerful prophylactic. "Where the teeth," says Dr. L. S. Parmly, "are kept literally clean, no disease will ever be perceptible. Their structure will equally stand the summer's heat and winter's cold, the changes of climate, the variation of diet, and even the diseases to which the other parts of the body may be subject from constitutional causes."

The configuration and arrangement of some teeth is such, however, as to preclude the possibility of keeping them clean, but this should not deter any one from using the proper means, for if disease is not wholly prevented, it will, at least, contribute very greatly to the preservation of the organs.

TREATMENT OF CARIES.

Although the physical condition of the teeth is sometimes such as to render them exceedingly susceptible to the attacks of caries, there is no disease to which the body is liable, that can be treated with a more certain prospect of success than this. If taken in time, it can almost always be arrested; and, if in the majority of cases it is not, it is attributable more to want of skill on the part of the dentist, than to the incurable nature of the disease. The treatment,

to be effectual, must be thorough, and there is no branch of manual medicine that requires more judgment, or a greater amount of skill, than the one within whose province the treatment of the disease under consideration, comes.

As a general rule, before any treatment is instituted for the purpose of arresting its progress, the gums and alveolo-dental periosteum should be in, at least, a tolerably healthy condition; for, if they are inflamed, or ulcerated, or in a highly irritable state at the time, the most skillfully applied remedies may prove unavailing. If, therefore, these structures are diseased, such treatment as may be necessary to their restoration, and which will hereafter be described, should first be had recourse to.

The treatment for arresting the progress of caries consists in two operations—filing and filling. The first is for superficial caries on the lateral or approximal surfaces of the teeth, and as preparatory to the other, when the disease is situated in the sides of the organs. The second is for deep seated caries, and the manner of performing each will be described in the two following chapters.

CHAPTER SECOND.

FILING TEETH.

THERE is no operation in dental surgery, against which a stronger or more universal prejudice prevails, than that of filing the teeth; and when judiciously and skillfully performed, there is no one more beneficial, or effectual in arresting the progress of caries. Thousands of teeth are every year rescued from its ravages, and preserved through life, by it. But, although it is productive of so much good, it is also, in the hands of ignorant and unskillful operators, productive of incalculable injury.

With regard to the merits of this wrongly judged and much abused operation, the author's views are so fully expressed by the late Dr. John Harris, in a paper published in the September No. of vol. 5, of the American Journal of Dental Science, that he cannot do better than quote his remarks upon the subject.

He says, "Filing the teeth is one of the most important and valuable resources of the dental art; it is one that has stood the test of experience, and is of such acknowledged utility, as to constitute of itself, in the treatment of superficial caries on the lateral surfaces of the teeth, one of the most valuable operations that can be performed on these organs. And even after caries, in the localities just mentioned, has progressed so far as to render its removal, by this means, impracticable or improper, the use of the file, in most cases, is still necessary, in order to the successful employment of other remedial agents. But in either case, a failure to accomplish the object for which it is used, would only be equivalent to doing nothing at all.

“The use of the file, then, may very justly be considered a *sine qua non*, for the removal of superficial caries from the sides of the teeth which come in contact with each other, as can be attested by thousands of living witnesses, and in preparing the way, in deep-seated caries, for the thorough removal of the disease, and filling, successfully, the cavity thus formed.

“In a paper written by myself, some eleven or twelve years ago, upon this subject, I contended that filing the teeth was not necessarily productive of caries, and my subsequent experience and observations have only tended to confirm the correctness of the opinion which I then advanced, and I cherish the belief that this opinion will not, at this time, conflict with the views of the more enlightened of my professional brethren.

“But when reference is had to the physical peculiarities of the teeth, it will at once be perceived, that they present a strange departure from the laws that govern and control all other parts of the body—that these organs, when diseased, can only be restored to health and usefulness by art, unaided by the sanitary powers of nature. Hence it is, that most of the operations upon them, will not, like those in general surgery, admit of mediocrity in their performance.

* * * * *

“The fact that the crowns of the teeth are covered with enamel, is alone sufficient evidence of its importance and utility in shielding and protecting the bony structure which it envelops, from mechanical and morbid influences, so that it would seem that its removal or loss would necessarily expose the organs to certain destruction. But we have satisfactory evidence, that teeth, after having suffered the loss of large portions of the enamel, have been restored to health, and preserved for many years, and often through life.

“The rapidity with which caries of the teeth progress, after the exposure of the bone, by the loss of the enamel, depends upon the physical peculiarities of the organs, and

upon local and constitutional influences; hence the difficulty, and oftentimes impossibility of obtaining the object for which dental operations are instituted, while such influences are suffered to exist. If special regard is not had to the curative indications, most, if not all the operations upon the teeth, which have for their object their ultimate preservation, are sure to a greater or less extent, to augment all of the previously existing local affections, by increasing the irritability of the parts, and by rendering them more susceptible of being acted upon both by local and constitutional causes.

“Without indulging in further prefatory remarks, I shall proceed to notice more particularly the subject under consideration. And I would observe, firstly, that an experience obtained from twenty-three years’ constant practice, has fully convinced me, not only of the propriety, but of the absolute necessity in the treatment of caries in the lateral surfaces of the teeth, of employing the file. There is no instrument so well adapted as this for the removal of the disease when situated in these parts of the teeth, and especially, when the organs are in close proximity with each other, or for the removal of rough and weakened edges of the enamel in deep-seated caries, and for making sufficient space or room for the removal of the diseased parts preparatory to plugging.

“It may be laid down as a rule, from which exceptions should never be taken, that the file should not be used, while the teeth or their contiguous parts are suffering general or local, acute or chronic, inflammation. Therefore, when this is the case, the treatment of the general and local affections should be precedaneous to the operation of filing. Upon the removal of all the acute or chronic diseases of the mouth, the success of the dentist in the treatment of affections of the teeth, calling for the employment of the file, greatly depends. As much importance, therefore, is to be attached to an enlightened and discriminating judgment, as to tact in the performance of the operation.

“In fact the removal of all local causes of irritation, such as all dead roots of teeth, teeth occasioning alveolar abscesses, or such as exert a morbid influence upon the surrounding parts, and all depositions of salivary calculus or other foreign matter, should always precede all other operations upon these organs.

“The length of time necessary for the restoration of the parts contiguous to the teeth, may vary from a few days, or weeks, to months, depending upon the nature and extent of the disease, the general health of the patient, and the constitutional as well as local treatment to which they are subjected.

“But, in assuming the position, that filing the teeth does not, of necessity, cause them to decay, it is by no means to be inferred, that the operation can, in all cases, and under all circumstances, be performed with advantage or even impunity. By no means; its effects, like those of most other operations upon the teeth, when the curative indications are disregarded, or not properly carried out, are never passive. The employment of the file at an improper time, and in an improper manner, increases the liability of the teeth to decay, and augments the irritability of all the parts adjacent to them, and consequently their susceptibility of being acted upon by local and constitutional causes.

“The principal, and I believe, only objection, urged against filing the teeth, is based upon the erroneous belief, that the loss of any part of the enamel of these organs must necessarily result in their destruction. But, if this be true, why is it, as I have, on another occasion, asked, that the negroes of Abyssinia have such sound teeth as they are represented to have, since it has long been a custom with them to file all their front teeth to points, so as to make them resemble the teeth of a saw or those of carnivorous animals. Of course, large portions of the enamel and considerable of the bony structure, must be removed in the operation, and yet, we are credibly informed that their teeth

seldom decay. The same may be said of the Brahmins of India, who, from remote ages, have been in the habit of using the file, principally, I believe, for separating their teeth, and they, too, are noted for having fine teeth. I might refer to the people of other countries, with whom the same practice has long had an existence, but it is not necessary to go abroad for proof, when we have such an abundance of it at home, to establish the propriety and absolute necessity for the practice I am now advocating.

“With the people just referred to, it is evident that they file, principally, for the purpose of ornamenting their teeth, but with us, only as a remedial agent in the treatment of their diseases. The reason why their teeth are not so subject to disease as are those of the inhabitants of civilized countries, is attributable to the difference in their habits of life, modes of living, and the absence of the causes productive of the various diseases peculiar to civilization and refinement.

“But notwithstanding the utility and value of the operation, filing the teeth may be regarded as a predisposing cause of caries. But if this be true, it may be asked, why file at all? I answer, in this country, owing to the prevalence of the immediate or direct cause of caries, the operation is only performed as remedial, for the purpose of removing actual disease or as preparatory to plugging. It does not, of necessity, follow, that caries of the teeth, after having been judiciously removed or treated, although the organs be predisposed to the disease, should ever again occur. The general system often escapes the development of the diseases to which it is predisposed through life, so, also, do the teeth. If the operation be properly performed, and the filed surfaces kept thoroughly clean, a recurrence of the disease, notwithstanding the increased predisposition thus induced, will never again take place. The immediate cause of dental caries being the contact of corrosive agents with the teeth, the necessity for this precaution is obvious. The bony structure of these organs is more easily acted upon by

such causes, than the enamel, and for this reason, when it becomes necessary to expose it, with a file, for the removal of disease, should be done in such a way as to admit of its being kept thoroughly and constantly clean, so that if it afterwards becomes carious, it will be owing altogether to the inattention of the patient. In view of this, whenever it becomes necessary to file the teeth, whether for the complete removal of caries, or as only preparatory to plugging, we should always impress upon the patient the importance of attending to this matter—of cleansing the surfaces thus operated upon, at least three or four times every day. The future preservation of the organs, and especially when they are of a soft or chalky texture, for they are then, by far, more easily acted upon by decomposing agents than when hard, will depend upon the constant and regular observance of this precaution.

“The cases requiring the use of the file vary so much, that it would be difficult to lay down precise directions with regard to the extent to which the operation should always be carried. This must be determined by the judgment of the operator.

“The object for which the operation is performed, may be defeated either by filing too much or too little. Either extreme should be avoided, but I am of the opinion, that by far the greater number of unsuccessful results are attributable, rather to the too moderate, than to the too great use of this instrument, and especially, where the circumstances of the case have nothing to do in determining the result.

“But it is not my object to describe the manner in which teeth should be filed, but merely to offer a few general remarks on the advantages that result from it when the operation is judiciously performed, and to show that it is from the abuse of the use of the file, in the hands of the ignorant and inexperienced practitioner, that its merits have been so frequently erroneously estimated.

“It will be perceived from the foregoing remarks, that its

utility depends upon carrying out all the curative indications, that it should never be resorted to except in the absence of disease in the parts with which these organs are immediately connected. Therefore, to estimate the merits of the operation, correctly, we should know all the circumstances under which it has been performed, the competency of the operator, and whether he was permitted the free exercise of his judgment.

“The dentist is often called upon to render his services, where, from the timidity or ignorance of his patient, he is, if he consents to operate at all, so restricted in the application of his remedies, that but little, if anything more than temporary relief can be afforded. And cases may occasionally occur, in which, from unforeseen circumstances, even after the most skillful management, the dentist may be disappointed in his expectations, and fail in the attainment of the object for which his services were solicited.”

To secure the success of the operation, it is sometimes necessary to file away a considerable portion of the tooth, but in doing this, the operator should be careful not to destroy the symmetry of the labial surface. The aperture, anteriorly, should only be wide enough to admit of a free oblique or diagonal motion of a safe-sided file of about one-fourth of a line in thickness. In this way, one-fourth or more of a tooth may be removed without materially altering its external appearance. But a tooth should not be filed entirely to the gum; a projection should be left to prevent the approximation of it and the adjoining organ.

When the decay occupies a large portion of the approximal surface, and has penetrated into the tooth to a considerable depth, and destroyed the enamel anteriorly, causing it to present a ragged and uneven edge, it will be necessary to form a wider exterior aperture than correct taste would dictate. When the approximal surfaces of the two front teeth are affected with caries, about an equal portion, if circumstances will permit, should be filed from each tooth.

The accompanying engraving represents a front view of the superior incisors and cuspidati after having been filed.

FIG. 71.

It is scarcely necessary to give any directions with regard to the manner of holding the file. In filing the front teeth and those on the right side of the jaws, the operator should stand at the right and a little behind the patient, in order to steady his head as it rests against the head-piece or top of the back of the operating chair, with his left arm, while with the fingers of the hand of the same, the lips are raised and the teeth properly exposed for the operation. In filing the teeth on the left side of the mouth, it will be necessary for the operator to stand upon the same side of his patient. The file, firmly grasped between the thumb and middle finger of the right hand, with the end of the forefinger resting upon the edge of its distal extremity, should be moved backwards and forwards in a direct line, as any deviation from this would immediately snap the instrument. The first opening between the teeth, when the approximal edges of the two are carious, should be made with a flat file, of about one-fourth of a line in thickness, cut on both sides and both edges; this done, a file cut only on one side and both edges, should be employed for the completion of the operation. If but one tooth is decayed, the operation may be commenced and completed with a safe-sided file. The file, during the operation, should be frequently dipped in water, to prevent it from becoming heated or choked between the teeth.

After a sufficient portion of the tooth has been filed away, the surface should be made as smooth as possible with a very fine or half worn file, or Arkansas oil-stone, and a burnisher. The edges and sharp corners should be rounded and made smooth, and when the operation is completed, the patient should be directed to keep the filed surfaces perfectly clean, for if the mucous secretions of the mouth, or

extraneous matter is permitted to adhere to them, a recurrence of the disease will take place.

In separating the bicuspid, an aperture should be made somewhat in the form of the letter V; it should not, however, form an acute angle at the gum; and for its formation a file, shaped like the pinion-file of a clock, or one that is oval on one side and flat on the other, will be found most suitable. An aperture, shaped like this, will prevent the approximation of the sides of the teeth, and if filling be necessary, it will enable the operator to do it in the most perfect manner.

FIG. 72.

In Fig. 72 is represented a posterior view of the superior incisors and cuspidati after having been filed; also, a vertical view of the bicuspids and molars after having been subjected to the same operation.

When the separation of the molar teeth becomes necessary, the same shaped apertures should be formed. But as these teeth are situated so far back in the mouth, it cannot often be done with a straight file, and to obviate the difficulty, an instrument, with which every dentist is acquainted, denom-

FIG. 73.

inated a file carrier, is usually employed. But, in consequence of the difficulty of procuring instruments of this kind, exactly suited to holding files of the right shape, the

author, a few years ago, constructed some file patterns for this purpose, and through Messrs Canfield & Brothers, of Baltimore, sent them to Stub's manufactory, in England, and had files made, which he found to answer his fullest expectations.

These files, as may be seen by the foregoing cut, are shaped something like the pinion file of a clock: they are an inch and a half long, and have a handle of about six inches in length, bent in such a manner that the instrument may be used between the molar teeth without interfering with the corners of the mouth. These files are in pairs—one for the right and one for the left side of the mouth. But, in Fig. 73, two patterns are represented. The upper, in consequence of the handle being on a line with the file, works more easily than the lower one.

FIG. 74.

Fig. 74, represents a very useful and valuable file-carrier invented by Dr. A. Westcott. It is so constructed that the handle is brought on a line with the file—consequently two are required, one for each side of the mouth.

FIG. 74. The portion marked *c*, is a spring, and through the arms *a* and *b*, there are square mortices, to receive the ends of the file and to keep it from turning. It will be perceived, by examining the cut, that the arm *b* does not come off at right angles, and the object of this shape must be apparent. The file is prepared by making each end square, corresponding with the size of the mortices in the arms, and is adjusted to the carrier by first putting one end of the file into the arm *a*, and pressing down the other end into the mortice *b*, the spring constituting that portion of the instrument between the arm, which yields sufficiently to admit of this. It will be readily perceived that the file may be easily taken out, while it could not well be thrown in an opposite direction; also, that the arm *a* sustains almost the entire strain made upon the instrument; the arm *b* serving to steady the file, which is represented to the left of the detached portion of the instrument, marked *a*, *b* and *c*.

CHAPTER THIRD.

FILLING TEETH.

THIS is one of the most difficult operations the dentist is called upon to perform—it often baffles the skill of operators who have been in practice many years. It is, also, when well performed, the most certain and only remedy that can be applied for arresting the progress of deep-seated caries. But to be effective, it must be executed in the most thorough and perfect manner. The preservation of a tooth, may be regarded as certain, when well filled, and with a suitable material, if it be afterwards kept constantly clean. At any rate, it will never again be attacked by caries in the same place.

On this highly important operation, Dr. E. Parmly thus remarks—“If preservation is as good as a cure, this is as good as both, for the operation of stopping, when thoroughly performed, is both preservation and cure. And yet, it must never be forgotten, that this assertion is true only in those instances in which the operation is well and properly done; and, perhaps, it is imperfectly and improperly performed more frequently than any other operation on the teeth.

“There are reasons for this fact, into which every ambitious and honorable practitioner will carefully inquire.

“Although the books are explicit on this point, I deem it sufficiently important to deserve a few additional remarks, and yet I am perfectly aware that my time requires me to be extremely general in my observations. Let me say, then, that the following considerations are essential, and, therefore indispensable to success in this department of practice.

“*Firstly*—The instruments used must be of the proper construction and variety.

“*Secondly*—The metal employed must be properly prepared as well as properly introduced.

“*Thirdly*—The cavity which receives the metal, must be so fitted as to retain it in such a manner as to exclude not only solids, but all fluids, and even the atmosphere itself.

“*Fourthly*—The surface of the metal must be left in such condition as to place it beyond the reach of injury from food and other mechanical agents with which it must of necessity come in contact.

“*Fifthly*—The tooth thus stopped should be free from pain, and every known cause of internal inflammation.”

It is important, however, that the operation be performed before the disease has reached the pulp cavity; after this, the permanent preservation of the tooth in many cases may be regarded as more or less questionable. Still, under favorable circumstances, the author believes it may in the majority of cases, be performed with success. But, as the propriety and manner of filling a tooth after the pulp has become exposed, will hereafter come up for special consideration, as well, also, as the operation of filling the pulp cavity after the destruction of the pulp, it will not be necessary to enlarge upon these subjects at this time.

A tooth is sometimes exceedingly sensitive when the nerve is not exposed; but this need not deter the operator from removing the decayed part and filling the cavity, as the only inconvenience it will occasion the patient, will be a little suffering during the operation, and slight momentary pain for a few days, whenever any thing hot or cold is taken into the mouth. But when the sensibility is so great that the patient cannot bear the removal of the diseased part—a thing which very rarely occurs, it may be, in most cases, obtained by the application of chloride of zinc, to the cavity of the tooth for from three to six minutes. When this is done, care should be taken to prevent it from coming in contact with any of the soft parts of the mouth. The fortieth or fiftieth part of a grain of arsenic is sometimes applied, but there is great danger of destroying the vitality of

the pulp by the use of this agent, even though it be permitted to remain but for a few hours. Cobalt, it is said, is less dangerous and equally efficacious.

Filling teeth, is advisable only under certain circumstances, and when the operation is performed without due regard to these, it may be productive of injury rather than benefit.

MATERIALS EMPLOYED FOR FILLING TEETH.

Among the articles which have been employed for filling teeth, are, gold, tin, lead, gum mastic, silver, an alloy of bismuth, tin and lead, amalgam, and platina.

Gold Foil.—To the use of this material, when properly prepared, there is no objection. It is the only one, in the opinion of the author, which should ever be employed for filling teeth. No better material is wanted for the operation. A tooth, in almost every case, may be so filled with it as to secure its permanent preservation. It should, however, be perfectly pure, be beat into thin leaves, and well annealed before it is used. When prepared in this manner, it may be pressed into all the inequalities of the cavity, and rendered so firm and solid as to be impermeable to the fluids of the mouth.*

Although there may be no difference in the purity of the gold, and the thickness of the leaves, yet a marked and great difference will be found to exist in the malleability and toughness of the foil of different beaters. The art of preparing gold for filling teeth is an exceedingly nice and difficult one, and is believed has attained greater perfec-

* It would seem from what Fauchard says upon the subject, (*Le Chirurgien Dentiste*, tome 2, pp. 68 to 70,) that this metal, to some extent at least, has been used for filling teeth for a long time. Although he gives the preference to tin and lead, on account of the greater malleability of these metals, he speaks of gold as being used by other dentists. But the operation of filling teeth, at the time this author wrote, was very imperfectly understood, and the gold then employed for the purpose must have been so badly prepared as to render its use exceedingly difficult.

tion in the United States than any other country; or, at any rate, this fact is so generally admitted, that many of the most eminent European practitioners procure most if not all they use, from Mr. Charles Abbey, of Philadelphia, the oldest manufacturer in America. There are, however, many other gold beaters in the United States who manufacture gold foil of a very excellent quality.

The thickness of the leaves is determined by the number of grains each contains, and is designated by numbers on the books, between the leaves of which they are placed, after having been properly annealed. These vary from 4 to 20. For example, a book containing a quarter of an ounce of No. 4, will have thirty leaves in it. The weight of the leaves, generally, vary two grains, so that the numbers run, 4, 6, 8, 10, and so on up to 20. Some dentists, in their practice, use foil varying in Nos. from 4 up to 20, while others confine themselves to a single No. If but one No. be used, 4 will, perhaps, be found better than any other. The author has used Nos. 4, 6, 8, 10 and 15, but he prefers the first, and is decidedly of opinion, that in a large majority of cases, a better filling can be made with it than any of the others. There may be cases in which higher Nos. can be more advantageously employed.

Foil manufactured from sponge or crystalline gold, is so adhesive, that any number of pieces may be welded one to another, and by means of which, a part, or even the whole of the crown of a tooth, may be built up with it. The same properties may also be imparted to foil manufactured in the ordinary way, by re-annealing. This property is peculiarly valuable in many cases where it becomes necessary to build up a large portion of the crown of a tooth; but when it is used, instruments having integrating points are required, like those employed in the use of crystalline gold. But for filling ordinary cavities in teeth, this property is of no advantage; indeed, for filling a deep cavity, having an orifice no larger than the bottom, it is objectionable, as more time and labor is required to reach the same point of

excellence with it, than with foil such as is usually obtained from the best manufacturers.*

Sponge and Crystalline Gold have recently been employed by a few dentists for filling teeth, and although the anticipations of the profession generally have not been fully realized by these preparations, the experiments thus far warrant the belief that the last, at least, may be so improved, as to render it an exceedingly valuable acquisition to dental practice. The author has used it in a number of cases with very satisfactory results.

Since the publication of the fifth edition of this work, the properties of crystalline and sponge gold have been more thoroughly and extensively tested, and the result of subsequent experience, taken in the aggregate, especially with the last named preparation, has fully confirmed the favorable opinion, expressed in the preceding paragraph, with regard to its value. Those who have had most experience in the use of it, say it is superior, in many cases, to foil. The author is acquainted with several, and they among the most skillful operators in the United States, who have used it almost exclusively in their practice, for more than a year; and he has seen fillings made by some of these gentlemen, which for beauty and solidity he does not think can be surpassed, with foil. He has also made some with it himself, which he believes it would be impossible to make with ordinary gold foil. The crystals possess the property, when pressed firmly against each other, of welding and becoming as solid and almost as incapable of disintegration or crumbling as a piece of bullion or coin. This property enables a skillful manipulator to supply almost any loss which a tooth may have sustained, even to the building on of an entire crown. Still it will never supersede the use of gold foil, as there are many cases in which the latter can be used more advantageously

* Adhesive gold foil has been known to some dentists for many years, but Dr. R. Arthur was the first to describe the proper manner of using it, (*A Treatise on the Use of Adhesive Gold Foil*, p. 86, 1837,) and to show that the same point of excellence could be attained with it as with the best preparations of crystalline gold.

and with more facility than the former. Nor will the employment of it, in the opinion of the author, ever become universal, for the reason that more care and skill are required to make a good filling with it, especially when the cavity in the tooth is difficult of access, than with leaf-gold.

Tin Foil.—This, when chemically pure, and properly prepared, is less objectionable, than most of the articles hereafter enumerated, for filling teeth. Under favorable circumstances, if skillfully introduced it will prevent the recurrence of caries. But if the fluids of the mouth are vitiated, it soon oxydizes and turns black, and then, instead of preventing, it rather promotes a recurrence of the disease. This, with the author, has constituted an insuperable objection to its use. As an excuse for its employment, however, many operators say, that in consequence of its greater malleability than gold, it can oftentimes be employed for filling a badly-shaped and large cavity when the last named article cannot be used. We do not, however, regard this as a valid objection. Any tooth that can be filled with tin, can be equally well filled with gold. Others again employ it, because many of their patients are not able to pay for a more costly material. Now, if a tooth is worth filling at all, it is worth filling in a proper manner, and with a suitable material, and it would be more creditable to the operator to divide the expense with his poor patient, than to use an article that may never benefit him.

Lead is even more objectionable than tin, as it is more easily decomposed by the secretions of the mouth, and by being introduced into the stomach, might be productive of serious injury to the general health of the patient. But, happily, this article is now seldom used, except by the most ignorant and lowest class of empirics.

Gum Mastic, although at one time much used, is now seldom employed, except as a temporary filling when the pulp

of the tooth is exposed, and when used even for this purpose it requires to be often renewed, as it is soon dissolved by the saliva.

Silver.—This article is more easily oxydized by the septic (nitrous) acid of the mouth than tin, and, in consequence of its greater destructibility, is more objectionable than the last named metal. Besides, it is harder and more difficult to consolidate.

The alloy of Bismuth, Tin, and Lead, or D'Arcet's Metal, as it is sometimes called, is used in a state of fusion. It was never, however, very popular, as the temperature required to fuse it being that of boiling water, was apt to excite inflammation in the tooth and its membranes. It was also found, that upon cooling, it shrunk, and admitted the fluids of the mouth between it and the walls of the cavity of the tooth. Its use, therefore, has been discontinued.

Amalgam, better known by the name of *mineral cement,* or *lithodeon,* is the most pernicious material that has ever been employed for filling teeth. It almost always oxydizes in the mouth, turning the teeth black, and often hastens their destruction. When used in considerable quantity, it is apt to exert a deleterious effect upon the alveolo-dental membranes, gums, and other parts of the mouth.

In the first edition of this part of his work, the author expressed his disapprobation of the employment of this article, and since that time he has had abundant opportunity of observing its effects, and he is fully confirmed in the unfavorable opinion which he then expressed with regard to it. Several decided cases of salivation, occasioned by the use of it, have fallen under his observation.

Some have endeavored to obviate the objections existing to its use, by employing silver perfectly pure; but it matters not how pure this metal may be, the amalgam is equally deleterious in its effects. Nor would it be any better if pure

gold were substituted for silver. It is the mercury that does the mischief.

Platina Foil, from its capability of resisting the action of the acids of the mouth, would, if it were sufficiently malleable, be unobjectionable, but when in a pure state, it is too hard to admit of thorough consolidation in the cavity of a tooth. A perfect filling, therefore, cannot, without great difficulty, be made with it. For this reason, it is seldom used.

INSTRUMENTS FOR FORMING THE CAVITY.

For the removal of the diseased part of a tooth, and the formation of a cavity for the proper reception and retention of a filling, a variety of instruments are required, which should be constructed from the best steel, and so tempered as to prevent them from either breaking or bending. Their points should be so shaped, that they may be conveniently applied to any part of a tooth, and made to act readily upon the portion which it may be necessary to remove.

The instruments employed for this purpose are called excavators. They may be formed either with, or fitted to, separate handles, or be made to fit into one common handle, provided with a socket for the purpose. Those having separate handles are more convenient than the others, but

FIG. 75.

it would be well for every practitioner to be provided with a number of both kinds.

The flat and burr-headed drills are very useful for enlarging the orifice of a cavity. When these are formed, each with a handle, the pressure of the instrument against the hand, between the thumb and fore-finger, is often productive of much irritation. To prevent which, a socket ring or shield like the one represented in Fig. 75 or 76, may be used with great advantage.* It consists of a ring adapted to the fore or middle finger, with a small socket attached to the inside, as shown in Fig. 75.

FIG. 76.

The author uses an open ring like the one represented in Fig 76, with an arm of a little more than an inch in length, attached, having a socket at the extremity resting in the hollow of the hand, between the thumb and fore-finger. This he finds much more convenient, as it enables him to apply more pressure upon the instrument without irritating the finger, and as the ring is open, it adapts itself more readily to it.

A socket-handle, however, will be found very useful, and when used, should have a spring attached to it for the more perfect retention of the instrument. Some handles have only a simple socket for the reception of a burr-drill, but the one with a spring is preferable. This may not only be used for holding drills, but it also answers for every description of excavator. The drill is also used in a stock, turned with a string and bow. This method of using it is objected to by some because it is supposed it is productive of more irritation to the tooth than when the drill is moved simply with the thumb and fore-finger.

The instrument represented in Fig. 77, is a modification of a very ingeniously contrived drill-stock invented by Dr. Maynard, for opening a cavity in the grinding, buccal or posterior approximal surface of a molar tooth. It is so con-

* The instrument as represented in cut 75, was invented by Dr. A. Westcott.

structed as to move a drill, pointing in three different directions, but, as in the case of the drill-stock used with a bow, the original instrument requires both hands to work it. To

FIG. 77.

obviate which difficulty, it has been so improved that it may be used with one hand, as may be seen by the above engraving.

FIG. 78.

Two drill-stocks were presented to the author some years ago, the first by Dr. James Robinson, of London, invented by Mr. McDowell, of Lincoln Inn Fields. This instrument, is represented in Fig. 78. It is upon the principle of the helix lever. A drill-stock is inserted at the end of the screw, moved by means of a female screw attached to

FIG. 79.

the handle of the instrument. As may be seen from the engraving, drills, pointing in three directions, may be worked in it. The other is from Mr. John Lewis, formerly of Burlington, Vt. This is represented in Fig. 79.

It is a beautiful and admirably contrived instrument. The drill may be moved in it, in any direction from a line with the handle to a parallel with the same.

For opening a cavity in the grinding surface of a tooth, partially covered by projecting portions of the enamel, the rose or burr-headed drill is invaluable, and it can very often be advantageously applied to the side of a tooth. There are many cases, too, where the flat triangular pointed drill can be conveniently employed, as for example, when it becomes necessary, as it often does, to extend the cavity further into the tooth than the disease has penetrated. A three-sided instrument brought to a point, as also a chisel-edged, and a four-sided one with a cutting edge, may often be used advantageously in cutting away portions of enamel to enlarge

FIG. 80.

FIG. 81.

FIG. 82.

the orifice. These instruments are represented in Figs. 80, 81 and 82. But the cavity can seldom be completed with either the flat or burr-headed drill, or either of the instru-

FIG. 83.

ments represented above. After it has been opened, and the orifice made sufficiently large, it should be finished with flat or curve pointed excavators, properly adapted to the purpose, and with instruments of this sort, it should, in fact, in the majority of cases, be wholly formed.

When, however, the drill is used, it should be frequently dipped in water to prevent it from becoming heated by the friction which it produces. This precaution ought never to be neglected.

FIG. 83. *a, b, c, d, e, f, g*, excavators for the removal of caries in different localities in teeth.

Excavators, shaped like those represented in Fig. 83, have been found by the author as well adapted for the removal of carious portions of teeth as any which he has ever employed. But every dentist should have several like each of these, and each varying in size from the other.

As the proper formation of the cavity greatly depends on having suitable instruments, every operator should be provided with a large supply of burr-drills and excavators, so that he may never be at a loss for such as may be required by the peculiarity of any case which may present itself. He ought, also, to be supplied with the means, and in case of emergency, be able to make them himself. It is important, too, that these instruments be always sharp, and as they soon become dull, he should have a good oil-stone at hand, upon which he may, at any moment, sharpen them. The Arkansas oil-stone, on account of its great durability, and fineness and sharpness of grit, is, on some accounts, preferable to any other.

MANNER OF FORMING THE CAVITY.

The formation of the cavity in a tooth for the reception of a filling, is very often an important part of the operation, and though usually the easiest, is sometimes attended with much difficulty. The removal of the diseased part is not always all it is necessary to do, preparatory to the introduction of the gold. The cavity must be so shaped, as when properly filled, to prevent the liability of the filling from coming out. The part of the tooth, too, surrounding the orifice, should present no rough or brittle edges or points. The bottom of the cavity should be as nearly the size of the orifice as it is possible to make it, and it would be better to have it even a little larger than any smaller. But the difference between the size of the one and the other should never be very great. If the interior of the cavity is much larger than the orifice, it will be difficult to make the filling sufficiently firm and solid to render it absolutely im-

permeable to the fluids of the mouth; and if, on the other hand, the orifice is larger than the bottom of the cavity, it will be difficult to obtain sufficient stability for the filling, to prevent it from ultimately loosening and coming out. It often happens, however, that the situation and extent of the decay is such, as to render it impossible to make the cavity as large at the bottom as at the orifice, and when this is the case, several pits or circular grooves should be cut in the inner walls, for the purpose of obtaining as much security for the filling as possible. By properly attending to this precaution, a filling may be so inserted as to prevent it from coming out.

As a general rule it is easier to form a cavity in the grinding surface of a molar or bicuspid, than in any other tooth or part of a tooth, though it sometimes happens, that even here, it is attended with difficulty, and especially when the decay, commencing in the centre, follows the several depressions which run out from it. In cases of this sort, the edges bordering on and covering the affected parts, which are often thick and very hard, should be cut away, together with the subjacent decayed dentine, and these radiating excavations should open fully into the central cavity, and made sufficiently wide and deep to admit of being filled to their extremities in the most perfect and substantial manner. The surface of a filling occupying a cavity of this kind presents a sort of stellated appearance. When two or more decayed places, separated only by very thin walls of tooth substance, these should be cut away and a cavity formed large enough to include all the diseased points, as one large filling will secure the preservation of the tooth more effectually than by filling each cavity separately.

Before a cavity can be prepared in the approximal surface of a tooth, it is usually necessary to separate the organ to be operated on from the adjoining one. This may be done either with a file, or by pressure, operating between the teeth in opposite directions. Each of these methods has its

preference. When caries has extended over nearly the whole of the approximal surface, so that after the removal of the diseased part, the orifice of the cavity will be surrounded by a thin, brittle and irregular wall, and in individuals in whom there is a decided scorbutic tendency, or who have suffered from the use of mercurial medicines or syphilitic disease, and in aged persons, the former is the preferable method. But when the caries has spread over only a small portion of the surface of the tooth, and is surrounded by sound, healthy enamel, the latter method, in individuals in whom there is no manifest tendency to inflammation or sponginess of the gums, and especially in young subjects, should be adopted. The manner of separating teeth with a file, has been already described; it will only be necessary, therefore, in this place, to offer a few remarks on separating by pressure.*

The following are the advantages of the latter over the former method, where it can be resorted to with safety; namely, after the removal of the pressure, the teeth almost immediately come together, leaving no aperture to injure their beauty; and what is of still greater importance, the dentine around the external surface of the filling is not exposed to the action of the secretions of the mouth, or other agents capable of exerting upon it a deleterious effect. On the other hand, some are of opinion, that by the approximation of the teeth, a lodgment is afforded to corrosive agents, upon the presence of which the disease was, in the first instance, produced, and which would, of necessity, soon cause a recurrence of it. In replying to this objection, it is only necessary to observe, that the parts of teeth first attacked by caries, were the points in contact with each other, where the enamel may be supposed to have sustained some injury by pressure and friction, thus rendering them more vulnerable at these points to the action of the causes that produced the disease. By properly replacing the dis-

* This method of separating teeth was first adopted by Dr. Eleazar Parmly, of New York.

eased parts with gold, the external surfaces of the fillings will be the only parts that come in contact with each other in such a way as to render them liable to injury from the above mentioned mechanical causes; and the enamel around them, if proper attention to cleanliness be observed, is not so liable to be acted on by chemical agents as the dentinal parts of the organs.

But teeth cannot always be separated by pressure with impunity; it can only be done with safety in certain cases. As a general rule, the writer is of the opinion that it ought not to be attempted after the thirtieth or fortieth year of age, though it doubtless may sometimes be done with safety at a later period. The diseased action, excited for the time, in the sockets of the teeth, does not so readily subside, at a later age, and it has in some instances, been known to result in the loosening and ultimate loss of the organs. In one case which came under the observation of the author, the inflammation extended to the lining membrane and pulp, causing their disorganization, and as a consequence, the death of the tooth.

The pressure ought never be too actively exerted; it should be gradual and constant. From four to twelve days are usually required for the separation of two teeth sufficiently for the removal of the decayed part and the introduction of a filling. After they have been separated in this way, they should be kept apart, without any increase of pressure, until the soreness in the sockets shall have subsided, before any farther steps are taken in the operation. Only two teeth should be separated in the front part of the mouth, in the same jaw, at the same time.

The pressure is usually made by the introduction of a thin wedge of soft wood, a piece of gum elastic, tape, or a little raw cotton, between the crowns of two teeth, replacing it every day or two with a thicker piece. The writer prefers gum elastic to any other substance he has employed for the purpose. But the object may be readily attained with other substances.

But whether the teeth be separated with a file or by pressure, the aperture should be sufficiently wide to enable the dentist to operate with ease; otherwise, it will be impossible to remove the caries and fill the teeth in a proper manner.

After every particle of decomposed dentine has been removed, the cavity should be thoroughly cleansed before the filling is introduced. This may be done by first injecting tepid water into it with a properly constructed syringe, and afterwards wiping it dry with a small lock of raw cotton fixed upon the point of a probe or excavator; or, the cavity may, in the first place, be wiped with a little raw cotton, moistened with water, and afterwards with dry cotton. Some recommend tissue paper for drying the cavity, for the reason that it absorbs moisture more readily than cotton. The latter, however, is the most convenient, and is equally as good as the former. Its absorbing qualities may be increased by boiling it for fifteen or twenty minutes in a tolerably strong alkaline solution. When this is done, it should be thoroughly washed and dried before using. It is desirable that the cavity should be perfectly dry before the filling is introduced.

INSTRUMENTS FOR INTRODUCING GOLD FOIL.

For introducing and consolidating the gold, a number of instruments are required, which should be sufficiently strong to resist any amount of pressure the dentist may be capable of exerting in the operation. They should have round or octangular handles, large enough to prevent the liability of being broken, and to enable him to grasp them firmly in his hand. Their points should vary in size, though none should be very large. Several should be straight, but for the most part, they require to be curved—some very slightly, others to form with the shaft of the instrument an angle of ninety degrees. Most of them should have a slim wedge-shape. Some, however, both of the straight and

curved instruments, should have blunt serrated points, and a few should have highly polished oval points, for finishing the surfaces of fillings in the grinding and other exposed surfaces of teeth. Formerly most dentists employed for introducing and consolidating the gold, simple blunt-pointed pluggers; but, it is impossible with such instruments to make a filling as firm and solid as it should be for the perfect preservation of a tooth, and especially if the cavity is large. From one-fourth to one-half more gold can be introduced into a tolerably large cavity, with a wedge-pointed than with a blunt-pointed instrument.

The sides of the wedge-pointed pluggers should be left a little rough, for the purpose of preventing them from cutting the gold, and there should be two or three small notches filed across their edges. When thus prepared, the gold can be more perfectly controlled and more readily conveyed to the bottom of the cavity than with smoother edged instruments. The blunt pointed instrument, or those used for condensing the extruding extremities of the folds of gold, should, as before stated, have serrated points, that the surface of the metal may be thoroughly integrated in the process of consolidation.

This general description will serve to convey a tolerably correct idea of the description of instruments required for the operation; but, no two dentists have their filling instruments precisely alike; each has them constructed in such a way as he thinks will enable him to apply them most easily and efficiently to the various parts of a tooth which may require filling. In the chapter on filling individual cavities in teeth, cuts of most of the instruments employed in the operation will be found.

Instruments with points somewhat differently constructed, are required for filling teeth with crystalline or sponge gold.

MANNER OF INTRODUCING AND CONSOLIDATING GOLD FOIL AND
FINISHING THE SURFACE OF THE FILLING.

The operator, being provided with the necessary instruments, should cut his gold with a pair of scissors, into strips of from half an inch to an inch wide. Each of these should be loosely rolled or folded together lengthwise, and after the cavity has been properly cleansed and dried, the end of one should be introduced and carried to the bottom of the cavity, with a straight or curved wedge-pointed instrument; the roll on the outside should then be folded on the part first inserted. The folding should be commenced on one side of the cavity, and the inner end of each fold taken to the bottom, the outer extending nearly a twelfth or an eighth of an inch on the outside of the orifice, and thus, fold after fold is introduced, until no more can, in this manner, be forced into the cavity. Having proceeded thus far with the operation, the instrument should be forced through the centre of the filling, and the gold firmly pressed against the walls of the cavity. The opening thus made should be filled in the manner as first described, and this time it should be packed in as tightly as possible. This done, the operator should endeavor to force in a small wedge-pointed instrument, at the side or some other part of the cavity; and thus he may proceed until he has tried every part of the plug; filling, as he proceeds, every opening which he makes, and exerting, in the packing of the gold, all the pressure which he can put on, without endangering the tooth. If one roll or fold of gold is not enough, he may take another and another, until the cavity is thoroughly filled.

The advantage to be derived from introducing the gold in this manner is obvious. By extending the folds from the orifice to the bottom of the cavity, the liability of the gold to crumble and come out, is effectually prevented, and by introducing it with a wedge-pointed instrument, it may be

pressed out into all the depressions of the walls of the cavity, and rendered altogether more solid than it could otherwise be made. The adhesiveness of the gold may be increased by slightly annealing in the flame of a spirit lamp, after it has been made into rolls or folds.

After the cavity has been completely filled, every portion of the projecting part of the gold is thoroughly consolidated, either with a straight or curved small blunt-pointed instrument, as may be most convenient; or if the filling is in the side of a tooth facing another, it may be compressed with the angle of the point of the plugger, making the adjoining organ a kind of fulcrum for the instrument. After the filling has been thus consolidated, as long as it can be made to yield in the least to the pressure of the instrument, the protruding parts may be scraped or cut, if in the grinding face, and filed, if in the side, down to the tooth, so as to form a smooth, uniform, gently swelling or perfectly flat surface. If in this part of the operation any portion of the gold should crumble or be dislodged, which it will not do if it has been properly introduced and consolidated, the injury may be repaired by making in the part of the plug, where it has occurred, an opening, and filling it, or by the removal of the whole of the filling and the introduction of another. Every part of the surface of the filling should be uniform and free from the slightest indentations which may afford a lodgment to clammy mucus or extraneous matter of any sort. This is a point which should never be lost sight of, for, however excellent the filling may be in other respects, if the surface is not smooth, uniform, and flush with the orifice of the cavity, the object intended to be accomplished by it will be partially if not wholly defeated. If any portions of the gold have been forced over the edge of the orifice of the cavity, they should be carefully removed, either with a file or sharp-pointed cutting instrument suited to the purpose. This precaution should never be neglected, especially when the filling is in the approximal surface of a tooth where a portion of the

gold is very liable to be forced up or down upon the neck, as the tooth may happen to be in the upper or lower jaw.

After having prepared the surface of the filling in the manner as here described, it may be rubbed with finely powdered pumice stone, or, with what is by far better, a small piece of Arkansas oil-stone, until all the file scratches or other asperities are removed. If the filling is in the grinding, buccal or palatine surface of a molar or bicuspid, a long piece of the stone, having a small triangular and slightly oval point, may be used, or, if powdered pumice stone be employed, it may be used on the point of a similarly shaped piece of soft wood, previously moistened in water. For a filling in the approximal surface of a tooth, the oil-stone may be shaped like the pinion file of a clock, and in either case it should be frequently dipped in water, and when its pores become filled with gold, the surface may be ground off by rubbing it on a corundum slab; or if pumice is used, it may be applied with floss silk, moistened with water, by drawing it backwards and forwards across the surface of the filling.

After all the asperities have been removed, the surface should be washed until every particle of grit is removed. This done it may be polished with a suitable burnisher, dipping it in water from time to time, having a small quantity of pure castile soap dissolved in it, until the filling is rendered as brilliant as a mirror. Having proceeded thus far, it may be again washed, and the operation completed by rubbing it from three to six minutes with dry floss silk.

When the caries has penetrated nearly to the pulp cavity, the presence of a gold or any other metallic filling, is sometimes productive of considerable pain and irritation, especially when hot or cold fluids are taken into the mouth, or during the inspiration of cold air. In some cases, inflammation and suppuration of the lining membrane and pulp supervenes. To prevent these disagreeable effects, a variety of means have been proposed. Dr. Solyman Brown recommends placing asbestos, this being a non-conductor of

caloric, on the bottom of the cavity, previously to the introduction of the gold. Others recommend placing a thin piece of cork, and others, again, oiled silk, between the filling and the bottom of the cavity. The author prefers a thin layer of *gutta percha*. This is less destructible than either of the two last named articles, and can be more conveniently and more perfectly applied. It may be used in the form of a thick solution, prepared with chloroform, or a layer of thin *gutta percha* cloth may be placed at once in the bottom of the cavity. When the solution is used, a drop may be placed in the cavity, and a sufficient time allowed for the chloroform to evaporate, before introducing the filling. A thin layer of "Hill's stopping," of which *gutta percha* forms the principal ingredient, may be used with equal advantage.

The time required to fill a tooth well, by an expert operator, may be said to vary from thirty minutes to two hours and a half, according as the cavity is large or small, or favorably or unfavorably situated, and in some cases a much longer time will be required. The author has found it necessary in filling some cavities, especially when the restoration of a large portion of the crown was called for, to bestow as many as six hours constant labor upon the operation. Much less time and skill are usually required to fill a cavity in the grinding than in the approximal surface of a tooth, and the operation in either place to be beneficial to the patient, must be performed in the most thorough manner, and the dentist who does not feel the importance of making such an operation, should never be entrusted with the management of the disease of these important organs.

In every part of the operation, the dentist should so guard his instruments as to prevent them from slipping, and he will usually be better able to do this by standing a little to the right and behind his patient than in any other position. In filling the lower teeth he should stand several inches higher than while filling the upper, and to enable him to do this, he should be provided with a stool, to be

used whenever he may find it necessary to occupy a more elevated position. When it can be done, he should grasp the tooth with the thumb and fore-finger of his left hand, not only to prevent it from being moved by the pressure he applies, but also to catch the point of the instrument in case it should slip; but if he is always careful to press in a direction towards the orifice of the cavity, this need never happen, but, nevertheless, he should always use the necessary precaution to prevent such accident. When he cannot shield the mouth with the thumb and finger of his left hand, he should let the thumb or one of the fingers of his right rest either upon the tooth he is operating on, or upon some other.

For the manner of filling individual cavities in teeth, the reader is referred to the next chapter.

CHAPTER FOURTH.

FILLING INDIVIDUAL CAVITIES IN TEETH.

To describe the method of filling each individual cavity in every locality in which a tooth is liable to be attacked by caries, would be both tedious and difficult. But, as this is one of the most important, and, at the same time, one of the most difficult operations in dental surgery, it may be well to enter a little more into detail upon the subject, than we have as yet done. But in doing this, the writer will confine himself, for the most part, to the manner of filling a cavity in each of the following localities, which are the parts of teeth most liable to become the seat of caries.

First.—In the approximal and labial surfaces of the superior incisors and cuspidati, and palatine surfaces of the former of the above mentioned classes of teeth—the latter being rarely attacked by caries on their posterior surface.

Second.—In the grinding, approximal, buccal and palatine surfaces of the molars and bicuspidi of the upper jaw.

Third.—In the approximal surfaces of the inferior incisors and cuspidati.

Fourth.—In the grinding, approximal, and buccal surfaces of the molars and bicuspidi of the lower jaw.

Other parts of the teeth sometimes become the seat of caries, but the foregoing are the localities most liable to be attacked by the disease.

FILLING THE SUPERIOR INCISORS AND CUSPIDATI.

In describing the manner of introducing a filling in one of the first named teeth, we shall commence with the right

approximal surface of the left central incisor. The directions we propose giving for the performance of the operation here, will be applicable to the same surface, with a few exceptions, of all the upper incisors. As a general rule the gold should be introduced from behind the teeth forwards and upwards, and for the following reasons: 1. When the aperture between the teeth has been formed with a file, it should, when the circumstances of the case will permit, and for reasons stated in another place, be made wider behind than before, consequently, the diseased part can be most easily approached from this direction. 2. The gold, in the majority of cases, can be more conveniently introduced from the palatine side, and the force required for condensing it can be more advantageously applied.

The exceptions to the above rule, are, when the approximal side of the tooth is turned slightly forwards towards the lip, and when the caries is situated nearer the labial than the palatine angle; also, when the teeth, instead of occupying a vertical position in the alveolar border, or projecting slightly as they usually do, incline backwards towards the roof of the mouth. It sometimes happens, too, when they are separated by pressure, that the diseased part can be most conveniently reached from before.

The instrument which the writer has found best adapted for the introduction of the gold in a cavity in the right approximal surface of an incisor or cuspid tooth, is represented in Fig. 84. The width and length, as well as the curvature or angle of the point, should vary according to the size of the cavity and the width of the aperture between the teeth.

Fig. 84.

The stem of the instrument as well as the shank should be strong enough to sustain any amount of pressure which it may be necessary to apply in forcing the folds of gold

tightly against each other. The point should be wedge-shaped, and the extremity serrated.

The decayed part of the tooth having been removed, and the cavity properly shaped, cleansed and dried, is ready for the reception of the gold.

The patient may be seated in a chair sufficiently high to bring his head on a level with the breast of the operator, and recline on the head-piece of the chair with the face upwards. The patient being thus seated, the operator standing upon the right side, should support his head firmly with his left arm during the operation, while with the thumb and fore-finger of the hand of the same, the strip or roll of gold is held, and one end placed in a proper position to be introduced into the cavity of the tooth. The middle finger of the same hand, ought, at the same time, to rest on the end of a tooth to the left of the one on which the operation is being performed, while with the little finger the lower lip may be gently depressed.

During the introduction of the gold, the instrument (see Fig. 84) should be held in the right hand of the operator in the manner as represented in Fig. 85, but grasped with sufficient firmness to prevent it from slipping or rotating.

FIG. 85.

In introducing the gold, the first fold should be applied against the upper wall of the cavity, that the pressure may always be exerted in a direction towards the extremity of the root,

applying each additional fold as closely to the preceding one as possible. The folds should, also, in their introduction, be applied as closely to the labial and palatine walls of the cavity as possible, but always directing the pressure, when these are thin and brittle, in a direction towards the axis of the root.

When the lower part of the orifice of the cavity is very narrow, as is often the case, especially when it extends nearly to the labial angle of the tooth, it is often necessary to change the instrument for one having a smaller point.

To carry a fold of gold upon the point of the instrument, without breaking or cutting it, to the bottom of a cavity in a tooth, requires some tact. The point should never be carried directly towards the bottom of the cavity. On entering the orifice, it should be directed towards the wall of the cavity opposite the one against which the folds are first laid. Equally as much tact, too, is required to prevent displacing the gold before a sufficient quantity has been introduced to procure support for it from the surrounding walls. This last is an accident particularly liable to occur with young practitioners, when the cavity is superficial and has a large orifice. To prevent this, the folds of gold should be long enough to project a considerable distance from the orifice, that they may receive some support from the adjoining tooth, and the thumb and fore-finger of the left hand of the operator. In this way the gold may be prevented from being moved or displaced, until the operation has arrived at that stage when sufficient support and stability shall have been obtained for it from the walls of the cavity.

There are some cases in which an instrument like the one represented in Fig. 86, can be very advantageously employed in the introduction of the gold; but in the majority of cases, the instrument represented in Fig. 84 will be found more convenient and efficient than this.

FIG. 86.

After having filled the cavity so thoroughly that a small wedge-pointed instrument cannot be made to penetrate the gold at any point, the extruding portion of the filling should be consolidated, beginning with the overlapping portions upon the lower part of the tooth and edge of the posterior wall. These should be carefully and firmly pressed in the direction of the orifice of the cavity, with an instru-

ment like the one represented below. This done, it may be firmly applied to every part of the surface of the filling, repeating the pressure as long as the point of the instrument can be made to indent the gold.

FIG. 87.

When the space between the two teeth is too narrow to admit the application of an instrument like the one represented in Fig. 87, one having a differently shaped point may be used. See Fig. 88. The operator should be provided with two or three instruments like each of the two

FIG. 88.

last, varying both in the size, length and curvature of their points. Sometimes, he will be able to use one with more efficiency than another.

During the process of consolidating the gold, the tooth should be firmly grasped between the thumb and fore-finger of the left hand of the operator, to prevent it from being pushed too forcibly against the opposite side of the socket, while, at the same time, the end of the fore-finger, by being placed above the instrument, assists in directing the application of its point, and serves to prevent it from slipping.

When the labial and palatine walls of the cavity are very thin, great care is necessary to prevent fracturing them, in introducing and consolidating the gold. The consolidating should be commenced around the edges, and the pressure applied in a direction towards the centre of the cavity.

It sometimes happens that the caries extends forwards to the labial and approximal angle of the tooth, extending upwards, at the same time, above the termination of the apex of the gum. Great difficulty is often experienced, in cases of this sort, in thoroughly filling this portion of the cavity, and it cannot always be done from behind the tooth. In this case, after having filled the cavity in the manner as already described, the operator may take a position on the left side of the patient, and with an instrument having a wedge-shaped point, bent like the one represented in Fig.

89, make as large an opening as possible in the gold. This done, he may grasp the left lateral incisor, or cuspid tooth with his thumb and

Fig. 89.

middle finger of his left hand, elevating the upper lip with the fore-finger of the same; then, with the instrument held in his right hand, in the manner as represented in Fig. 90, he may proceed to introduce the gold, filling the upper part of the opening first. After introducing fold after fold, until it is completely and compactly filled, the extruding portion may be consolidated with a similar shaped instrument, having a round serrated point, or an instrument like the one represented in Fig. 88.

The size of the roll of gold may be varied to suit the size of the cavity, though it should seldom have in it more

Fig. 90.

than a fourth of a leaf of No. 4. If more than this be employed at one time, it will be difficult to apply them sufficiently near together.

When the teeth have been separated by pressure, or when the aperture is as wide anteriorly as posteriorly, the gold may be introduced from either side as may best suit the convenience of the operator; but, when introduced from before, it may be done in the manner as just described, the operator standing on the left side of his patient, and using such instrument as he may find best adapted for its intro-

duction. Sometimes the one represented in Fig. 84, will be found best suited to the purpose; at other times, the one represented in Fig. 89 can be most advantageously employed.

The gold having been introduced and condensed, the surface of the filling may be finished in the manner as already described.

In describing the manner of filling the right central incisor in the left approximal surface, it will not be necessary, as the method of procedure is so very similar to that of filling the left in the right side, to enter so minutely into detail. In this as in the other case, the gold, as a general rule, should be introduced from behind the tooth, forwards and upwards. But no matter from which side it is introduced, the operator should stand on the right side of the patient. The head of the latter, too, should have the same elevation, and the same inclination backwards, but the face should be turned more towards the operator to give him a better view of the cavity in the tooth, and to enable him to reach it more readily with the instrument.

The patient being seated, the cavity formed, cleansed, and dried, the operator may proceed to introduce the gold in the manner as already described, with an instrument like the one represented in Fig. 84. In many cases, however,

FIG. 91.

he will require one having a somewhat longer point, and curved to nearly a right angle with the stem. But what-

ever be the length and curvature of the point, the instrument should be held somewhat differently in the hand, (see Fig. 91,) and grasped so firmly with the thumb, and fore and middle fingers, as to prevent it from rotating. The head should be securely confined with the left arm, the upper lip elevated with the thumb of the hand of the same, pressing it at the same time firmly against the anterior surface of the tooth. The middle or fore-finger, as may best suit the convenience of the operator, of the same hand, may be placed on the gum of the palatine surface, to direct the application of the point of the instrument, prevent the liability of its slipping, and control the free end of the roll of foil. The lower lip may be depressed either with the middle joint of this, or with any of the other fingers.

After having placed one end of the gold in the cavity, fold after fold may be introduced, as before directed, until it is compactly filled, except in those cases where the lower part is very small, when, after having filled all but this portion, a smaller pointed instrument should be employed for the completion of the operation, and, indeed, for the introduction of the whole of the gold if the cavity is not large or the aperture between the teeth very narrow.

For consolidating the extruding gold, the instrument represented in Fig. 87, will, in many cases, be all that is required. But in addition to this, others are often needed. The one represented in Fig. 92, can sometimes be used very advantageously. The one in Fig. 93, may often be efficiently employed in some parts of the operation of condensing in the right, as well as in the left approximal surface of an an incisor, or cuspid tooth.

FIG. 92.

FIG. 93.

Both of the last mentioned instruments may often be used to great advantage on the approximal surfaces of other teeth. The instruments represented in the chapter on filling teeth with crystalline and

sponge gold, Fig. 118, may also be advantageously employed in consolidating the gold in the approximal surfaces of the incisors as well as in other teeth.

The gold having been properly introduced and consolidated, the remaining part of the operation may be completed as before directed. But in doing this, it may be well to observe, that while it is important that every particle of gold overlapping the orifice of the tooth, and frequently extending under the free edge of the gum, should be removed before finishing the surface of the filling. The operator ought, at the same time, to avoid as much as possible, wounding the point of the gum and dental periosteum.

As the cavity in the tooth frequently extends not only to the gum, but sometimes a little above it, great care is necessary to prevent wounding it, and indeed there are many cases, in which it cannot be avoided, unless the dentist uses the precaution to press the point of it up between the teeth, by the introduction of a piece of raw cotton, or gum elastic, a day or two before the operation of filling is performed.

In filling an incisor, or cuspid tooth in the labial surface, the operation is often very simple, and easy of performance, but there are many cases in which it is both difficult and tedious. The head of the patient should rest upon the head-piece of the chair, with his face upward in the manner as already described, and sustained in the same way with the left arm of the operator, while with the thumb of the hand of the same placed on the gum above the tooth, the upper lip should be elevated.

FIG. 94.

The fore-finger may be pressed firmly against the palatine surface of the tooth, and the left side of the chin gently grasped with the middle, annular and little fingers. Then with an instrument, like the one represented in Fig. 94, having a wedge-shaped point, grasped with the right hand, in the manner as seen in Fig. 91, or 95, as may be most convenient, the operator may proceed to introduce the gold, standing at the right

side of the patient, with the thumb of the right hand resting on a tooth to the left of the one he is about to fill, or against the cheek, he should commence by laying the first folds against the wall of the cavity nearest to him, and thus introduce fold after fold, until it is thoroughly and com-

FIG. 95.

pactly filled. The extruding portion may be consolidated with a round or square pointed instrument having the same bend, or with a straight pointed one as represented in Fig. 96. But in this part of the operation, great care is necessary to prevent the instrument from slipping and wounding the gums. After having partially consolidated the gold, the overlapping portion may be firmly pressed towards the orifice of the cavity, then the point of the instrument should be repeatedly applied to every part of the surface of the filling, until it can no longer be made to yield to pressure. This done, the gold may be filed down to a level with the surface of the tooth, ground with Arkansas oil-stone, and burnished or polished.

FIG. 96.

When the cavity is shallow and the orifice broad, the gold as it is introduced must be held in place, with the thumb of the left hand, until a sufficient quantity has been placed in the cavity to obtain for it the necessary support from the surrounding walls. But in overcoming difficulties of this sort, the peculiar circumstances of the case can alone suggest the proper means to be employed by the operator.

The decay sometimes extends entirely across the labial surface of the tooth, leaving, after its removal, a horizontal groove open at both ends. In this case, the walls should be made rough, or wider at the bottom than at the opening, and the operation of filling commenced at one end, by applying the folds of foil, first, against either the upper or lower wall, as may best suit the convenience of the operator, and carrying them across to the other, and consolidating them so thoroughly as to prevent the liability of their being displaced during any subsequent part of the operation. Another and another series of folds are introduced in the same manner as the first, and each in close contact with the preceding series, until the groove is completely filled, applying the pressure during the whole of this part of the operation in the direction of the two walls. In condensing the extruding gold, the operator may commence, first at one end of the groove, then at the other, and afterwards proceed with the process of consolidating over the whole surface of the filling.

In finishing the operation, the same precaution, with regard to wounding the gum and dental periosteum, should be observed here as recommended for the approximal surface of the tooth.

Although it rarely happens that the palatine surfaces of the upper incisors are attacked by caries, yet the disease does sometimes develop itself there, in the indentations occasionally found a little below the free edge of the gum.

But the removal of the diseased part, the formation of a cavity, and the introduction of a filling, can, in the majority of cases, be more easily accomplished in this, than in any other part of an incisor tooth.

The cavity being properly prepared for the reception of the filling, and the head placed as before directed, except that the chin may be a little more elevated, to enable the operator to obtain a more convenient view of the locality of his operation, the thumb of the left hand may be placed on the labial surface of the tooth, and the fore-finger on the

gum immediately above the palatine surface. He may now, with a wedge-pointed instrument, shaped like the one represented in Fig. 97, proceed to introduce the gold, applying the first fold against the palatine wall of the cavity, or the palato-approximal angle of the wall, as may be most convenient. Having filled the cavity, the extruding gold may be condensed with an instrument like the one represented in the annexed cut. See Fig. 98.

FIG. 97.

FIG. 98.

Sometimes straight instruments, and at other times instruments curved at the points more than those represented in Figs. 97 and 98, can be more efficiently and conveniently employed, depending altogether upon the size of the mouth and the forward or backward deviation of the teeth from a vertical arrangement in the jaw. This is a matter, therefore, which the judgment of the operator, in view of the peculiarities of the case, can alone determine.

FILLING THE SUPERIOR MOLARS AND BICUSPIDS.

In describing the manner of filling a cavity in each of the principal localities liable to be attacked by caries, in the above mentioned teeth, the writer will begin with the grinding surface of the first molar on the right side. The directions he will give with regard to the manner of filling a cavity here, with a few exceptions, will be applicable to the introduction of a filling in the grinding surface of any of the upper molars or bicuspid.

When the cavity is very deep, and its circumference not very large, it is difficult, if not impossible, to make a filling sufficiently firm and solid in every part by the introduction of folds of gold long enough to extend from the bottom to the orifice. The operation, therefore, should be divided into two parts; namely, the upper half or two-thirds of the cavity should be first thoroughly filled, and afterwards the remaining lower part, with vertical folds.

In filling a molar or bicuspid in any of its surfaces, the head of the patient should, for the most part, occupy very nearly the same position, and have the same elevation as required for the performance of the operation on an incisor or cuspidatus. The cavity being prepared for the filling, and one end of the roll of foil placed in it, the tooth may be grasped with the thumb and fore-finger of the left hand of the operator—the former placed on the buccal surface in such a manner as to press back the commissure of the lips, and the latter on the palatine surface, then fold after fold may be introduced and forcibly pressed against the posterior wall until the cavity is filled. For this purpose an instrument may be used like the one represented in Figs. 94, or 96, as may best suit the convenience of the operator. If the former is used, it may be grasped as shown in Fig. 91. After which the extruding portion may be condensed with a straight instrument like the one represented in Figs. 96, 98 or 99, as may be most convenient.

As a general rule, filling a cavity in the grinding surface of an upper molar or bicuspid is an exceedingly simple operation, requiring less skill than the introduction of a plug in any other locality in these teeth, but there are cases in which it is rendered very difficult; as for example, when there are one or more fissures or carious depressions radiating from the main cavity. To fill these thoroughly, after the diseased parts have been removed, which last is often a very tedious operation, requires considerable time and skill. When it is not properly done, as is too often the case, a recurrence of the disease will soon take place, and thus defeat the object for which the operation is performed.

The introduction of a filling in the grinding surface of the second or third molar of a person having a very small mouth, is sometimes attended with great difficulty, and in some cases, can only be done with an instrument having a point bent at nearly right angles with the stem, like the

Fig. 99.

one represented in Fig. 99, consequently the power required for introducing and consolidating the gold is applied to great disadvantage. But the instrument represented in this cut is only intended for the first part of the operation of consolidating the metal. For the completion of even this, smaller points are required.

In filling a cavity in the grinding surface of a first upper molar on the left side of the mouth, the thumb of the left hand may be placed against the left cuspid or first or second bicuspid as may be most convenient to the operator, while the fore-finger is placed behind the point of the instrument, and at the same time made to push back the commissure of the lips. To obtain a good view of the cavity in a second or third molar during the operation, the cheek should be pressed from the tooth with the fore-finger of the left hand, but this finger can seldom be carried far enough back on this side of the mouth to be placed behind the point of the instrument. During the introduction of the gold, the annular and little fingers of the right hand should be made to rest on the incisor teeth, while the instrument is grasped with the thumb, middle and fore-finger in the manner as seen in Fig. 91.

In filling a cavity in the anterior approximal surface of a right superior molar or bicuspid, the operation may be commenced by placing the gold against the palatine wall, and ending at the buccal. But before the process of condensing is commenced, every portion of the surface ought to be thoroughly tested with a wedge-pointed instrument, and wherever the point can be forced into the gold, the cavity thus formed should be filled. The instrument employed for the introduction of the gold may be like the one represented in Fig. 84, but having a rather longer point; and grasped in the manner as represented in Fig. 91. For condensing the extruding portions, either or both of the instruments represented in Figs. 86, and 92 may be used, as also the one employed for the introduction of the gold; and one like the following, see Fig. 100, may be sometimes used with great

advantage. During this part of the operation, the instrument may be held in the manner as last represented, or as seen in Fig. 101. A much greater amount of force can be applied when it is held in this manner than in the other.

FIG. 100.

FIG. 101.

Nearly the same method of procedure, and the same instruments are required for filling a tooth in the same surface on the opposite side of the jaw. When practicable, the fore-finger of the left hand should be placed on the palatine surface of the tooth, and the thumb against the buccal surface, and in addition to the instruments recommended for the right side

of the mouth, the one represented in Fig. 86 may be very conveniently employed in introducing the gold, as can also

FIG. 102.

one like Fig. 88, or the following, Fig. 102, in condensing the surface of the filling. The writer finds this last particularly valuable in very many cases.

A cavity in the posterior approximal surface of a bicuspid in the superior maxillary of either side of the mouth, can, in the majority of cases, be as easily filled as one in the anterior approximal surface. The position of the left hand is very nearly the same, and in the introduction of the gold, the first folds are placed against the palatine wall of the cavity. By commencing the operation on this side, the operator is enabled to lay the folds more compactly than he could, were he to commence at any other part. He also has a more perfect control over the instrument he employs in this part of the operation, and, besides, it affords him a better view of the cavity during the introduction of the

gold. For consolidating the filling, the instruments represented in Figs. 87, 88 and 93, are, perhaps, as well adapted to the purpose as any that can be employed.

When the mouth of a patient is large, a filling can often be introduced with nearly as much ease and convenience, in the posterior approximal surface of a first, or even a second upper molar, as in the same surface of a bicuspid; but when the mouth is small and the cheeks fleshy, it often becomes an exceedingly difficult and perplexing operation. Although the same method of procedure is used, yet, as it is absolutely necessary to the introduction of a good filling, that the operator see the cavity and witness every part of the operation; his ingenuity is often taxed to the utmost, in contriving the most suitable means to enable him to do it. A number of instruments for drawing back the corner of the mouth have been invented; but, after all, the writer believes there are none so well suited to the purpose, as the thumb or fore-finger of the left hand of the operator.

Before dismissing this part of the subject, there is one point to which the attention of the young practitioner should be particularly directed. The part of the operation in which many, in other respects tolerably good operators, are most likely to fail, is, in not introducing a sufficient quantity of gold in the upper palatine portion of the cavity. The author frequently meets with cases in which every other part of the filling is well consolidated, and the walls of the cavity perfectly sound in every other place but this, and which, upon the application of a wedge-pointed instrument is easily perforated. He would, therefore, advise the inexperienced operator to thoroughly test this by severe pressure with a sharp wedge-pointed instrument, as well, indeed, as every other part of the filling, before leaving the operation. There is also one other precaution that should be attended to, and this remark will apply with as much force to fillings in the approximal surfaces of the incisors and cuspids as to the molars and bicuspids; it relates to overlapping portions of gold on the side of the tooth under the free edge of the

gum. These must be carefully and completely removed before the operation can be regarded as complete.

In filling a cavity in the buccal surface of an upper bicuspid or molar, on either side of the mouth, the gold may be introduced with an instrument like the one represented in Fig. 84, or Fig. 94, as may best suit the convenience of the operator. The latter is better adapted for the left side, and may also be used on the right. The straight wedge-pointed instrument too, may be advantageously employed on this side. In the introduction of the gold, the first folds should be placed against the posterior wall, and thus this part of the operation may proceed from behind forwards, pressing the folds against each other as compactly as possible.

When the cavity has a large orifice, and is rather shallow, or in other respects badly shaped for the retention of the gold, the operation is often tedious, difficult and perplexing. But under favorable circumstances, a filling may be as readily introduced here as in almost any other part.

The palatine surface of a bicuspid is rarely attacked by caries nor does the disease very frequently develop itself on this side of a molar, and when it does, it is usually seated in a depression at the termination of a fissure leading from the posterior depression in the grinding surface. The depression first mentioned is usually situated near the posterior palato-approximal angle of the crown about equidistant from the gum and the coronal extremity of the tooth. It sometimes happens that the walls of these fissures are affected with caries throughout their whole extent, requiring, after the removal of the diseased part, a filling reaching from the depression in the grinding, to its termination on the palatine surface. In this case, the portion of the cavity on the grinding surface may be first filled, then the operator may proceed to fill that portion of it in the palatine surface, in the same manner as if it were a simple cavity, placing the first folds of foil against the upper and posterior side of the opening, if it be in a tooth on the right side of the

mouth, with an instrument like the one represented in Fig. 94. But in doing this, great care is necessary to prevent the instrument from slipping. It often happens, too, that the orifice becomes choked with foil before the cavity is half filled. This, indeed, is liable to occur in filling any cavity in any tooth, and when it does happen, unless a sufficient amount of pressure is applied to make a free opening into it, the filling will be imperfect, and the object of the operation wholly defeated. When the cavity is situated in a left molar, the gold may be introduced with an instrument like the one represented in Fig. 84, or 97, as may be most convenient, placing the first folds against the upper wall of the cavity, and proceeding from thence towards the lower.

The curvatures of the points of the condensing instruments may be similar to those employed for the introduction of the gold. The process of condensing the extruding portion of a filling in the buccal or palatine surface of a molar, as well as in the approximal surface of almost any isolated tooth, may be greatly aided with properly constructed forceps. The following cut will convey a more

FIG. 103.

correct idea of their construction than any description that can be given. They are provided with both straight and curved points, see Fig. 103, *a*, *b*, *c*, and used by placing the flat jaw, covered with raw cotton or a cushion, against the sound side of the tooth, and the condensing point against the filling, which is made to act on it by pressing the handles towards each other. In this way as much pressure may be exerted upon the filling as the tooth will bear. It

is only, however, in the fewest number of cases that this instrument can be advantageously employed. The credit of the invention, it is believed, belongs to the late Dr. H. H. Hayden.

A tubercle, of greater or less size, is sometimes found on the anterior palatal part of the surface, near the coronal extremity of the tooth. Between this and the body of the crown, a deep depression is often seen, which becomes the seat of caries, but the removal of the diseased part, and the introduction of a filling is so simple, that a special description of the operation is not deemed necessary.

FILLING THE INFERIOR INCISORS AND CUSPIDATI.

The operation of filling a lower incisor or cuspidatus, is, by far, more difficult than filling an upper. It is fortunate, therefore, both to the dentist and mankind generally, that the incisors and cuspidati of the lower jaw, are less liable to be attacked by caries than the upper.

The constant tendency of the lower jaw to move and change its position, is embarrassing to the dentist in operating on any of the teeth in it, and on the incisors and cuspidati it is sometimes peculiarly perplexing. To prevent this, all the effort the operator can exert with his left hand, is frequently required. From the backward inclination, too, of these teeth, it rarely happens that the gold can be introduced from the lingual side of the arch, consequently, it is necessary to make the aperture as wide anteriorly as posteriorly. But as these teeth are, comparatively, very small, the separation when made with a file, should be no wider than is absolutely necessary for the removal of the diseased part and the introduction of the gold. When, however, it can be done with safety, the separation may be made by the introduction of a piece of gum elastic or other substance between the teeth, in the manner as before described.

But before we proceed further it may be well to remark, that while operating on the teeth of the lower jaw, the head

of the patient should occupy a more perpendicular position than while operating on those of the upper, and it may be made to do this, either by lowering the seat or raising the head-piece of the chair. When by the latter, it will be occasionally necessary for the operator to stand upon a stool five or six inches in height.

In filling a cavity in the right approximal surface of a lower incisor or cuspidatus, the following method of procedure may be adopted. The cavity being prepared, and a sufficient quantity of gold foil to fill it made into a small roll, or folded lengthwise as the operator may prefer, with the left arm over the patient's head, the chin is gently grasped with the hand of the same, while the thumb is placed against the lingual surface of the tooth—the fore-finger serving to direct the gold and point of the instrument, and to also depress the lower lip. The folds of gold in their introduction are pressed firmly against the lower wall of the cavity. The instrument employed for this purpose may be shaped like the one represented in Fig. 104, with a very small wedge-shaped point, and held in the right hand, in the manner as seen in Fig. 91. The consolidation of the extruding gold may be effected, partly with the same instrument, partly with a round pointed one, in other respects shaped like the one shown in Fig. 105, and partly with an instrument shaped like the one represented

FIG. 104.

FIG. 105.

in Fig. 93. But in this part of the operation the tooth should be firmly held between the thumb and fore-finger of the left hand, to prevent it from being moved in its socket by the pressure of the instrument.

When the incisors are very small, and the caries has spread over a large portion of the side of the tooth, it is often difficult to form a suitable cavity for the retention of a filling, without penetrating to the pulp cavity. In cases of this sort, the patience and skill of the operator are fre-

quently taxed severely in obtaining a sufficiently secure support for the gold. But this he can usually do, if he can make the bottom of the cavity as large as the orifice, even though it have but little depth.

The manner of introducing a filling in the left approximal surface, is so very similar, it is scarcely necessary to give a separate description of the method of doing it. The left arm and hand, as well as the thumb and fore-finger are all disposed of in the manner as just described. The same instruments, too, may be employed for introducing and consolidating the gold, though, in the first part of the operation, the instrument represented in Fig. 89, may often be advantageously substituted for the one represented in Fig. 104.

Thus far, nothing has been said with regard to the introduction of a filling in the labial or lingual surface of either of the two classes of teeth now under consideration. Although caries rarely attacks either of these surfaces of a lower incisor, it does sometimes develop itself in the labial surface of a cuspidatus, but the operation of introducing a filling here is so simple, that a separate description of the manner of performing it is not deemed necessary.

FILLING THE INFERIOR MOLARS AND BICUSPIDS.

In filling a cavity in the grinding surface of a lower molar or bicuspid on the right side of the mouth, the operator may stand on the same side of his patient, and a few inches higher than while operating on an incisor or cuspidatus. With his left arm placed over his patient's head, the tooth may be grasped with the thumb and fore-finger of the hand of the same, while the middle finger is placed by the side of the chin, the other two should be placed beneath it. The gold may now be introduced with an instrument like the one represented in Fig. 97, and held in the manner as shown in Fig. 91, pressing the folds against the posterior wall of the cavity.

In condensing the gold after the cavity is filled, an instrument may be employed like the one represented in Fig. 98. Sometimes, however, an instrument like the one shown in Fig. 100, which may be held in the manner as seen in Fig. 85; but a greater amount of force can be exerted when held in the manner as represented in Fig. 101, previously wrapped with the corner of a napkin, to prevent the small part of the instrument from hurting the little finger. The kind of instrument, and the manner of holding it, will, after all, have to be determined by the operator. But during the introduction and consolidation of the gold, the lower jaw should be firmly held with the left hand of the operator, to prevent it from moving and from being too much depressed. This precaution is the more necessary, as the muscles of the lower jaw and ligaments of the temporomaxillary articulation are seldom strong enough to resist the amount of force required in the operation.

In filling a cavity in the grinding surface of a tooth on the left side, the dentist may sometimes operate to greater advantage by standing on the same side. In this case, the commissure of the lips may be pressed back with the thumb of the left hand, placing it on or against the tooth to be filled, while the fore-finger may pass in front of the chin, and the other three beneath it. As a general rule, however, he will be able to operate more conveniently by standing on the right side of his patient, and holding the tooth and chin in the manner as before directed. But, in either case, the gold, in its introduction, should be pressed against the posterior wall of the cavity.

The foregoing general directions, will, for the most part, be found applicable to the introduction of a filling in the approximal surfaces of the teeth under consideration. When the crowns of these are long, and the cavity situated near the gum, the operation is sometimes very difficult and tedious, requiring all the patience and skill the dentist can exercise to accomplish it in such a manner as to secure the object for which it is performed. And this diffi-

culty is increased when the shape of the cavity is unfavorable for the retention of the gold; or, in other words, when the cavity is shallow and has a large orifice. There is also another very serious difficulty which the operator frequently encounters in the introduction of a filling in the approximal, as well as in the buccal surface of a lower molar or bicuspid. It is this: the flow of saliva is often so profuse that the whole of the lower part of the mouth is completely filled, and the tooth inundated before it is possible to introduce a sufficient quantity of gold to fill the cavity. This not only retards the operation, but it also renders it more difficult and perplexing, for it is necessary to force out every particle of moisture from the cavity and from between the different layers of gold before the necessary cohesive attraction between them can be secured. If this is not done, or at any rate, if all the moisture is not forced from the cavity, and the gold sufficiently consolidated to render it impermeable to the fluids of the mouth, the operation will be unsuccessful.

For the purpose of obviating the last mentioned difficulty, a variety of means have been proposed, but the one principally relied on, consists in placing the corner of a soft fine linen napkin, or what is still better, fine tissue or bibulous paper, on each side of the tooth, so as to form a sort of dam or wall around it. This may sometimes be successfully done, but in many cases it will fail to accomplish the object, as it always increases the flow of saliva, and is more or less embarrassing to the operator.

In the introduction of the gold, it may be pressed against the buccal wall of the cavity on the right side, and against the lingual wall on the left side. Either of the instruments represented in Figs. 84 and 94, as may be best adapted to the peculiarities of the case, may be employed for the introduction of the gold, whether the cavity be situated in the anterior or posterior approximal surface of the tooth, and it may be held in the hand in the manner as shown in Fig. 91.

In filling a cavity in the lingual and posterior approximal angle of a first or second left bicuspid, and especially after the loss of the tooth behind it, and there is a backward inclination of the organ, great care is necessary to prevent the instrument from slipping and wounding the lower lip. The most convenient position for the operator in this case is on the left side and partly in front of the patient. The tooth may then be firmly grasped between the thumb and fore-finger of the left hand, or only the thumb pressed against the buccal surface of it, as the operator may prefer, but in either case it may be used as a rest for the annular finger of the right hand, during the introduction and consolidation of the gold. But the locality of the cavity is such, especially when the mouth of the patient is small, that it can only be seen with great difficulty. Hence the operator is constantly liable to place the point of the instrument on one side of the orifice against an overlapping portion of gold, which, when pressure is applied, is cut through or detached. The instrument then comes in contact with the hard smooth enamel, and unless the hand is so guarded as to control its motions, it is liable to slip and wound some part of the mouth, especially the lower lip. Indeed, this is an accident, which, unless proper precaution is observed, may occur in filling any tooth.

Among the principal difficulties which the dentist encounters in filling a cavity in the buccal surface of a lower molar, apart from that which he experiences in keeping the cavity dry until the gold is introduced, is the contact of the lower and inner part of the cheek with the tooth. But this may usually, at least, to a considerable extent, be prevented, and the commissure of the lips at the same time pushed back, with the fore-finger of the left hand of the operator, which serves, when the cavity is shallow and the orifice large, to hold the gold in place, until a sufficient quantity is introduced to obtain mechanical support from the surrounding walls. It is sometimes, however, attended with much difficulty, but in operating upon the bicuspids, it

is only necessary to depress the corner of the mouth to obtain free access to the cavity.

Since the publication of the sixth edition of this work, an instrument has been invented,* for the purpose of keeping the cheek from the buccal surface of the lower molars, depressing the tongue and holding the jaws at a sufficient distance, the one from the other. One portion of it, as may be seen from the engraving, consists of two guttered plates, one for the upper and one for the lower molars, connected by a screw, working in a vertical cylinder—the latter cut on the inside for the reception of the spiral bead of the former. By means of this contrivance, the guttered plates may be separated or brought near to each other, according to the distance it may be desired to keep the jaws apart. Around the connecting portions of these plates are two

FIG. 106.

rings, each about three-eighths of an inch in width. From the inside of the lower, a shaft a little more than three-fourths of an inch in length projects, on which a ring is placed, having attached to its lower surface a tongue-holder, shaped something like a hand, with a small bar at the extremities of the fingers. By means of the two rings belonging to this part of the instrument—the one sustaining, and the other around the projecting shaft, the tongue-holder may be adjusted to the position it should occupy, and made

* The instrument described above, was invented by Dr. C. C. Thomas, dentist, of Bastrap, La.

fast by tightening the screw in each ring. From the inside of the upper large ring, a square bar projects and passes into an extension socket, moved by a ratchet spring. To the extremity of this, a highly polished concave oval plate is attached by a ball socket. The bar, with its extension socket, may be lengthened or shortened, at pleasure—the concave oval plate at the extremity holding the lower part of the cheek from the tooth to be operated on, thus fully exposing the cavity in its buccal surface, and reflecting the light directly into it.

The author has not had an opportunity of testing the practical value of this instrument, but he is inclined to believe, having seen it in the mouth, that it may be advantageously used in some operations, especially in the left lower molars.

For the introduction of the gold on the right side, either of the instruments, represented in Figs. 84 and 94, may be employed, but on the left side the latter will, as a general rule, be found most convenient. A straight wedge-pointed instrument, as represented in Fig. 107, can often be advantageously used in introducing the foil in either of the right bicuspid, and sometimes even in the

FIG. 107.

first molar. In fact, this instrument can often be used efficiently in filling a cavity in the grinding surface of a molar of either jaw, but oftener in the upper than the lower. It is scarcely necessary to say, that the introduction of the gold should proceed from behind forwards.

FIG. 108.

The instruments represented in Figs. 87 and 96, may be used in consolidating the extruding portions of foil, as also the one represented in Fig. 93.

When the cavity is situated near the gum, or, as is often

the case, when the lower part of it is a little below its margin, the precaution of removing all the overlapping portions, and this sometimes constitutes a difficult part of the operation, ought never to be omitted. For this purpose, the file represented in Fig. 108, may be very advantageously used.* Some are made straight at each end, others are curved. These files are very useful, not only for the purpose just stated, but also for filing down the extruding gold of a filling in the approximal and other surfaces of nearly all the teeth.

It may be well to mention here, that in filling a molar or bicuspid on the left side in the upper jaw, whether in the grinding, approximal or buccal surface, the back of the chair, if so constructed as to admit of being moved, should be thrown five or six inches farther back, to lower the head of the patient and give the face a more horizontal inclination. By this means the operator is enabled to approach the locality of his manipulations with greater ease, thus enabling him to exercise a more perfect control over his instrument, as well as the corner of the mouth. But if the back of his operating chair is stationary, he should stand upon a stool of five or six inches in height.

The foregoing details, with regard to the manner of filling teeth, will serve as a general guide for the performance of the operation, and at the same time, give to the student and inexperienced practitioner, some idea of the amount of labor, accuracy of manipulation, and perfection of execution, it requires.

The manner of building on the whole or part of the crown of a tooth, will be described in a subsequent chapter.

* This most useful and valuable instrument was invented by Dr. Elisha Townsend, of Philadelphia.

CHAPTER FIFTH.

FILLING TEETH WHEN THE LINING MEMBRANE IS EXPOSED.

THE propriety of filling a tooth after the invasion of the pulp cavity by caries, without first destroying the pulp, is doubted by many practitioners. It is thought that inflammation and suppuration of the lining membrane and pulp, must as a necessary consequence, result from the operation. But Dr. Koecker, who was the first to recommend filling a tooth under such circumstances, cites a number of cases in which he performed the operation successfully. He also expresses the belief that, "on an average, five out of six teeth may be preserved alive, and rendered useful for a long space of time," after the lining membrane has become exposed. The author has been in the constant habit of filling teeth under such circumstances, whenever a favorable case presented itself, since 1846, and occasionally for nearly twelve years previously to this period, and his experience warrants the belief, that the vitality of a much larger relative proportion may be saved under skillful treatment. He believes he has been successful in at least fourteen cases out of every fifteen, since 1853, and it may be, as he has stated in another place, that when the treatment of teeth in which caries has penetrated to the pulp-cavity shall be better understood, the vitality of a still larger relative portion may be preserved. At any rate, so long as it can be done in even nine cases out of ten, the operation must be regarded as valuable, for a healthy living tooth is less liable to become obnoxious to the surrounding parts than one deprived of a large portion of its vitality.

The fact that teeth can, in very many cases, be preserved alive after the lining membrane has become exposed, being admitted, the question arises, does the pulp remain in the condition in which it is at the time the operation is performed? It is difficult to conceive how a vacant space can exist between it and the filling, or that a foreign body can remain in contact with it, with impunity. Drs. Harwood, of Boston, and J. H. Foster and W. H. Dwinelle, of New York, are of the opinion, from experiments they have made, that it ossifies. That some change of this sort does take place, is well known, and the transition is evidently the result of increased vascular action, caused by irritation. Examples of this kind are met with in teeth in which the crowns have lost a considerable portion of their substance from mechanical or spontaneous abrasion, and it is a beautiful provision of nature to prevent the exposure of these delicate and highly sensitive parts. The same thing sometimes occurs in teeth which have suffered no loss of substance, and in this case, it is doubtless the result of some constitutional or local cause of irritation.

These facts, as we have elsewhere stated, would seem to justify the conclusion that the pulp of a tooth, when subjected, for a sufficient length of time, to the influence of an irritating agent, capable of exciting only a very slight inflammatory action, undergoes ossification; or rather is converted into a substance resembling *crusta petrosa*, or what Professor Owen terms *osteo-dentine*. When it fails to undergo this change in a tooth which has been filled after the lining membrane has become exposed, it is liable, from constitutional disease, or other causes, either to perish from derangement of its nutritive functions, or to become the seat of active inflammation and to suppurate. But something more than mere ossification, or its conversion into *osteo-dentine*, takes place when a space is left between it and the filling. If this vacant space was not obliterated, we have reason to believe that the slightest increase of vascular action would, as has been justly remarked by Dr. Elliot,

force a portion of the pulp into it, and thus brought in contact with the sharp angles of the walls of the cavity, active inflammation would be excited, and this, as a natural consequence, would be likely to terminate in suppuration. But we believe, from experiments which we have made, that nature, ever fruitful in her resources, uses means for the prevention of such an occurrence; consisting, first, in filling the vacant space with *coagulable lymph*, (*liquor sanguinis*,) effused from the lining membrane or exposed surface of the pulp—then, in its *organization*, and, lastly, its *conversion* into *callus* and *bone*, or more properly, *osteo-dentine*. Nature seems to employ the same means here that she does in other parts of the body, for the reparation of injuries.

When this reproductive process does not take place after the operation, it may be owing either to the want of increased vascular action in the lining membrane or pulp, or, to too much inflammation. A certain amount of increased vascular action seems necessary to the effusion of coagulable lymph, an indispensable requisite to it, but when this is too great, it must, of necessity, terminate in suppuration. This being the case, it is obvious that the success of the operation must very greatly depend upon the circumstances under which it is performed. However skillful the operator may be in the preparation of the cavity and the introduction of the gold, if these be unfavorable, his efforts to preserve the vitality of the organ, will in a large majority of cases, prove unavailing. The health of the patient should be unimpaired, the tooth of a tolerably good quality, free from pain at the time the operation is performed, it should never have ached, and the pulp, peridental membranes and surrounding parts be in a perfectly healthy condition. The cavity, too, should be of a proper shape for the easy introduction and permanent retention of the filling, and the smaller the point of exposure of the lining membrane, the greater the prospect of success. It is also important that every particle of completely decomposed dentine be removed

and if there be any oozing of blood from the ruptured vessels, this must cease before the filling is introduced.

The method of procedure, pursued by Dr. Koecker in the performance of the operation, is as follows :

First.—Remove the caries and give to the cavity a proper shape for the reception and retention of the filling; then free it of all dust that may be in contact with the pulp, with a little raw cotton moistened in warm water.

Second.—If the lining membrane is not wounded, dry the cavity, and place a small plate of thin leaf lead over the exposed nerve and surrounding dentine; then fill the cavity in the ordinary way with gold.

Third.—When the lining membrane is wounded and bleeds, canterize the part with an iron wire, heated to a red heat—using the precaution not to wound the pulp. After the hemorrhage has been arrested and an artificial cicatrix formed, free the cavity from all loose extraneous matter, in the manner as before directed, then cover the nerve with sheet lead and fill as before directed.

The reason assigned by Dr. Koecker for covering the nerve with lead, is that it has a “more cooling and anti-inflammatory effect” than gold. He also states that when he employed gold exclusively, he was seldom successful, and that inflammation, pain, etc., generally supervened, rendering the removal of the filling necessary.

The foregoing method of treating an exposed dental pulp has not proved so successful in the hands of other practitioners. It has been found that inflammation and suppuration supervene in a large majority of the cases, and especially, when the cautery is used—consequently, the practice is now seldom resorted to. The direct application of any metallic substance to the lining membrane or pulp, is, according to the observations of the author, very apt to be followed by inflammation and suppuration of these tissues. Some of the vessels of the lining membrane are always necessarily wounded in removing the last layer of decomposed dentine, but the hemorrhage, when no other injury

is inflicted, is very slight, and sometimes scarcely perceptible, so that the operation of filling need never be delayed more than from three to ten minutes. The application of a small particle of raw cotton moistened with spirit of camphor will immediately arrest it.

Dr. S. S. Fitch proposes to cover the nerve when exposed, with a plate of gold, previously to filling the cavity, and this, in the opinion of the author, is preferable to the direct application of a piece of leaf lead, as recommended by Dr. Koecker. It is certainly a better protection to the nerve, and if it be so fitted to the cavity that its edges shall rest upon the surrounding dentine, a filling may afterwards be introduced without injury to the pulp. Still, in very many cases the application of a covering of this sort is objectionable. It is difficult to fit it with sufficient accuracy to prevent the liability of its being displaced in the introduction of the filling; and when the cavity is very shallow it will often occupy so much room as to render it impossible to fill the remainder of it in a substantial manner, yet it may sometimes be very advantageously applied.

The plan pursued by Dr. J. H. Foster of New York, in filling teeth after the pulp has become exposed or is covered only by a very thin layer of dentine, is as follows: "If," says he, "after a careful removal of all the defective portion, within and about the parietes of the cavity, the thin layer of bone which lies adjacent to the lining membrane, has a moderate degree of consistency, yet not sufficient to protect the dental pulp from irritation caused by the pressure of external agents, it has been my practice to leave it there, and fitting a gold cap over it, (with great caution as to its proper adjustment as a protection,) proceed to fill the tooth." But this method of procedure, he says, was not as successful as he could have desired, depending, in a great degree, as he supposed, upon the extent to which the thin subjacent layer of dentine had been involved in diseases, and the liability of the pulp to be affected with heat and cold.

But to guard against the irritation and inflammation pro-

duced by this, he fills the concave surface of the gold cap with "Hill's stopping," using the precaution to preserve the concavity, so that it may not press upon the part it is designed to protect. This treatment, he says, has proved successful in a considerable majority of the cases. "Believing," says Dr. F., "that many failures occurred in consequence of the comparatively small portion of newly exposed bone which was covered and protected by the non-conducting medium, I resolved to try another experiment. Instead of lining the gold cap, after having fitted it accurately upon the floor of the cavity, I filled the whole of the cavity external to it, with Dr. Hill's composition, (which in its chemical properties and action is a harmless agent,) allowing this to remain for five or six months as a *temporary* stopping."

By this plan of procedure, Dr. F. says he has, with one or two exceptions, been successful in preserving the vitality of the teeth during the past year. He also states that he has occasionally removed these fillings after the lapse of two or three months, and finding the irritability of the tooth, still continued, he refilled them in the same manner and permitted the filling to remain two or three months longer, when, on again removing the stoppings, he found the inflammation diminished, and the subjacent layer of bone almost firm enough to bear the pressure of a gold filling; but he still uses the cap underneath the gold, as before. He believes, however, that if Hill's "stopping" could be relied upon for preserving the walls of the cavity for one or two years, as perfectly as it does for a few months, that the caps might be removed, and a solid gold filling introduced, without danger of causing irritation by pressure upon the bottom of the cavity.* Dr. F. further adds, that he has fre-

* The author will state one fact here, in connection with what Dr. Foster says in relation to Hill's "stopping." Mr. S. of Baltimore, applied to the author, in May, 1848, to fill the first left superior molar, which had a large cavity in its anterior approximal surface. On examination, it was found that the pulp had been destroyed, and that there was a discharge of fetid matter from the pulp cavity. As he was anxious to retain the tooth, the decomposed portions were removed, to the extremities of the roots, and the cavities injected, once a day, for some eight or ten days,

quently taken out gold fillings of his own insertion, "by way of experiment, which had been introduced under like circumstances, after they had been in for two or more years, and on removing the cap, had found the bone beneath so unyielding and void of sensibility, that he was able to introduce a solid gold filling without the cap."

The method pursued by the author, in filling a tooth after caries has penetrated to the pulp cavity, is a very simple one. The caries is removed and the cavity prepared in the usual manner, using the precaution not to wound the lining membrane if it can be avoided, though some of its vessels are always ruptured in the removal of the last layers of decomposed dentine; then, to wipe out the cavity very carefully with a dossil of raw cotton, saturated with spirit of camphor, which immediately arrests the effusion of blood from the minute capillary vessels. The gold is next introduced, commencing by placing the folds on one side of the cavity, and afterwards inserting fold after fold, without carrying those immediately over the exposed part of the lining membrane or pulp, to the bottom of the cavity, until every part, except a very small space immediately over the nerve, is thoroughly filled. The folds are forced so tightly one against the other, as to prevent the liability of pressing their inner extremities in the consolidation of the extruding portions of the filling against the exposed pulp at the bottom of the cavity. After the gold has been thoroughly condensed, the surface of the filling is finished in the manner as before described.

with a strong solution of chloride of soda. The fetid discharge had by this time apparently ceased; but still fearing, that if the tooth was filled, alveolar abscess would form, the author, with a view of ascertaining the effect which would be produced by the operation, filled the tooth with Hill's "stopping," requesting Mr. S. to call on him again in three weeks, if the tooth should occasion him no pain, or sooner if it should become troublesome. This he promised to do, but as he was much occupied with business, he neglected to keep his appointment. As the tooth gave him no uneasiness, he deferred calling from week to week, until nearly two years had elapsed. Recollecting, however, that his tooth had only a temporary filling in it, he, on the 25th of April, 1850, called to have it filled with gold. To the astonishment of the author, the walls of the cavity were found to be in as sound a condition as when the "soft-stopping" was introduced.

The author has occasionally placed a drop of the solution of gutta percha in the bottom of the cavity, and waited until the chloroform had completely evaporated, before introducing the gold. He has also used collodion in the same way. Dr. Elliot of Montreal, states in an article on filling teeth over exposed nerves,* that he places the gold "directly upon the living nerve, and in perfect contact with it, over the whole of its exposed surface," using, when the cavity is sufficiently deep to admit of it, *asbestos*, a non-conductor, "*enveloped in a few thicknesses of gold foil.*" He also says, that within the last year he had "but two cases in which irritation advanced so far as to become troublesome to the patient," and that in "both instances, perfect and permanent relief was obtained by the use of leeches and a mild cathartic." We are inclined to believe, however, that by leaving a vacant space between the filling and the pulp, the success of the operation will be rendered more certain.

The result of the operation, however, performed in either way, cannot always be immediately ascertained. Though it may at first be apparently successful, suppuration of the lining membrane and pulp may take place, three, six, or even twelve months after the introduction of the filling.

Dr. S. P. Hullihen, described to the author in the fall of 1851, a method which he had recently introduced of treating teeth after the lining membrane had become exposed. It consists, after filling the tooth in the usual way, of drilling a hole with a small spear-pointed drill, about a line above the edge of the alveolus through the gum, alveolar wall and root into the pulp-cavity, using the precaution not to separate the nerve, and wounding it as slightly as possible. The effusion of lymph resulting from the inflammation occasioned by the pressure of the filling, escapes through this opening, which, he believes, when the increased vascular action subsides, is filled with callus, and ultimately with dentine. Dr. H. informed the author he

* Am. Jour. Dent. Sci. No. 4, vol. 1, New Series.

had succeeded, by this method of procedure, in almost every instance in preserving the vitality of the tooth. The author has not performed the operation often enough to enable him to express an opinion with regard to its merits.*

Without going into detail, we have now, in as few words as possible given all the information we possess on the subject of filling teeth, with a view to the preservation of their vitality, after the lining membrane had become exposed; embracing the result of our experience since the publication of the fourth edition of this work, which, as the reader may perceive, has very greatly increased our confidence in the utility of the operation.

* From the very frequent failures of the operation, it is now very seldom if ever performed.

CHAPTER SIXTH.

FILLING PULP CAVITIES AND ROOTS OF TEETH.

THIS operation has now become very common. It is practiced, more or less, by many dentists, not only in America, but also in Europe, although the propriety of it is still doubted by many practitioners. The objection to the practice is founded upon the supposition, that, in proportion as the vitality of a tooth is lessened, it becomes obnoxious to the surrounding living parts.

It is contended that, though the presence of the tooth may not give rise to alveolar abscess, it is, nevertheless, to some extent, a local irritant, and as such, must, as a necessary consequence, exert a morbid influence, not only upon the living parts with which it is in immediate contact, but, also, upon the whole economy. Hence it is argued, that the proper remedial indication, after the death of the lining membrane, is the extraction of the tooth, and this reasoning, it must be admitted by all who have any knowledge of the laws of health and disease, is not without much seeming plausibility. Until comparatively recently, the result of most of the efforts made for the preservation and retention of teeth in this condition, fully justified its supposed correctness; for, in nine cases out of ten, the operation of filling, unless an opening was left for the escape of the matter secreted at the extremities of the roots, was followed, sooner or later, by alveolar abscess. The conclusion, therefore, that such teeth could not remain in the mouth with impunity, was a very natural one. But more recent experiments have shown it, to some extent at least, to be incorrect.

Drs. Maynard and Baker were the first to show that most of the morbid phenomena resulting from the presence of a tooth in the mouth after the destruction of the lining membrane, were caused by the irritation produced by the matter contained in the pulp-cavity and canal of the root. To prevent their occurrence, therefore, they propose filling both in such a manner as completely to exclude every thing else. The accumulation of matter here being prevented, its secretion at the extremity of the root, as has been shown by repeated experiments, will, in a majority of cases, either cease altogether, or go on no faster than it is carried off by the absorbents. Thus it would seem, that the amount of living principle a tooth derives from the investing membrane is sufficient, ordinarily, to prevent it from exerting any *manifest* morbid action upon the surrounding living parts.

Although it is desirable that the operation should be performed before any diseased action has been set up at the extremity of the root, much advantage may sometimes be derived from it even after alveolar abscess has actually occurred. Dr. Maynard informed the author, that he had succeeded in curing the disease by it. Other dentists have also done it, and the author has certainly known great benefit, in several instances, to result from cleansing and filling the roots of teeth which had given rise to abscess. The discharge of matter has, in most cases, on which he has operated, been greatly diminished, often subsiding altogether for several months at a time, and the recurrences rarely occasioning much inconvenience, or continued for more than a week, or ten days. Still, he does not feel warranted, from his own observations and experience, in recommending the operation in cases of this sort, unless the presence of the tooth is called for by some peculiar necessity.

During the year 1849, Dr. J. H. Foster filled the pulp-cavities and roots of forty teeth, with the following results:

	Alveolar Abscess.	Successful.	Unsuccessful.
3 Superior molars, . . .	1	3	
1 Inferior molar, inflammation without abscess, . . .	1	1	
9 Superior bicuspid, . . .	1	8	1
4 Inferior do. . . .	2	4	
7 Superior cuspidati, . . .	1	7	
2 Inferior do. . . .	1	1	1
13 Superior incisors, . . .	1	13	
1 Inferior do. . . .		1	

"In the case of the superior bicuspid, marked unsuccessful, Dr. F. says, the patient would not submit to the pain, and insisted upon the removal of the tooth during the incipient stage of alveolar abscess. In that of the superior cuspid, the abscess did not form until some months after the operation. It was opened in due time," but as the parts still continued painful, an attempt was made to remove the filling. This was unsuccessful, and as the pain continued, the tooth, which he had filled into the root from a cavity in the labial surface, was extracted. The fang was of an unusual length, and had a bold lateral curvature about three-fourths of the way up to the apex, rendering the passage of an instrument beyond the angle impossible. He had, however, forced the first piece of foil a little below this curve, which resisted all efforts for its removal. The fang below this point had become discolored and the periosteum inflamed.

The application of creosote to the inner walls of the sac, introduced through the canal in the root, previously to filling, has been recommended as the most certain means of cure that has ever been adopted.* The author has tried it with very gratifying results. It is introduced to the sac at the extremity of the root on the end of a thread of waxed floss silk, through the pulp-cavity and canal of the fang,

* The treatment of alveolar abscess with creosote preparatory to filling the pulp-cavity, was first recommended by Dr. C. W. Ballard.

previously freed of all extraneous matter. Another, and in some respects a better mode of applying this agent to the ulcerated inner surface of the sac, is to throw it into the tooth with a syringe, the opening in the crown being first closed with a piece of caoutchouc, with a perforation large enough to admit the tube of the instrument. The creosote is used in the form of a strong alcoholic solution, say one drachm of creosote to an ounce of alcohol. This being forcibly injected into the tooth, passes through the sac at the end of the root and escapes through the fistulous opening in the gum, where it is caught in a piece of soft moist sponge or a few folds of bibulous paper.* There are many cases, however, in which there is a slight morbid secretion that escapes through the tooth without any discharge from the gums. The most efficacious means of arresting this are the same as those recommended for the treatment of abscess of the socket. But the creosote in this case should be introduced in the manner as first described.

A professional friend† states, in a letter to the author, dated March 12th, 1850, that he has been for several years, and is now constantly in the habit of filling teeth and their fangs, after destroying their nerves, and also of cleansing and filling the cavities of the fangs of teeth which had previously lost their vitality,‡ and had become more or less diseased. He also states, that but very few cases had occurred in his practice, where ulceration had occurred, rendering the removal of the tooth necessary. He furthermore remarks, that whenever the investing membrane and gums of teeth, treated in this manner, become thickened and swollen, the symptoms are less severe. In proof of the correctness of this opinion, he has furnished the author with

* This method of applying remedial agents to the inner walls of the sac of an alveolar abscess, is recommended by Dr. F. H. Badger.

† Dr. E. J. Dunning, of New York.

‡ By the loss of vitality, we presume the writer means, that which the teeth derive from the lining membrane, for after the death of the investing periosteal tissue, a tooth becomes a foreign body, and must of necessity, be a constant source of irritation.

the following details of a case which came under his observation a few months since.

"A gentleman from the south called immediately after his arrival in this city, and stated that during his passage in the steamer, he had been suffering intensely from pain in a first superior molar. On examination I found the tooth thoroughly injected with red blood—the periosteum highly inflamed and considerably thickened, though there was no swelling of the gum. A small cavity in the posterior approximal surface had been filled with gold a day or two before sailing. In preparing the cavity for filling, arsenic had been used to allay sensibility.

"In most cases I should have advised the removal of the tooth, for the symptoms were most unfavorable to any operation for its preservation. But as the mouth was otherwise perfectly healthy, the arches unbroken, and the cavity in the tooth very small, and the patient extremely anxious to preserve it, I determined to try to save it.

"On examining the cavity carefully, I found that the nerve had never been exposed—the arsenic had acted upon it through the circulation, and had thus produced this severe inflammation.

"Having removed the layer of sound bone that covered the nerve, and finding it quite sensitive, I made an application of an exceedingly small quantity of a mixture of arsenic, morphine and creosote, and covered it with a metallic cap or arch, to prevent pressure, followed by a loose filling of tin foil. The pain and much of the soreness were immediately relieved.

"Saw the patient again on the fourth day—found the soreness entirely gone—had suffered pain since the application was made—injection remained the same. Found the part of the pulp contained in the central cavity entirely insensible—removed it; finding the portion in the fangs still sensitive, made the same application at the entrance of each canal and filled the cavity again with tin. At this sitting, ventured to file the tooth so as to increase the sepa-

ration between it and the second molar. The filed surface showed the injection beautifully, the bone appearing a bright red, and the line at the junction with the enamel very distinct.

"In three or four days saw the patient again, and to my surprise and delight found that the injection had entirely disappeared, and the tooth almost as perfect in color as any of its neighbors.*

"The nerves were then removed from the fangs, and their places filled with gold, and at a subsequent sitting, the external cavity was filled.

"As three months have elapsed since the operation was performed, without any news with regard to it, I conclude that it is thus far successful."

Other cases of a similar character, and with similar results might be given, but we will not enlarge further upon this part of our subject.

With regard to the best means for destroying the nerve, or rather the pulp of a tooth, there exists much diversity of opinion. Immediate *extirpation* with an instrument, *arsenic* and the *actual cautery*, are the ones most frequently employed, and each has its advocates.

To the use of arsenic and all similar agents, Dr. Harwood, of Boston, is strongly opposed. He states, in a letter to the author, dated February 13th, 1850, that "they cause death and sloughing in the parts to which they are more immediately applied, and irritation and unmanageable trouble in the parts next beyond those they absolutely

* The injection of the tooth from the vessels of the lining membrane and pulp, is of frequent occurrence in teeth to which arsenic is applied for the purpose of merely destroying the sensibility of the dentine. At the first meeting of the American Society of Dental Surgeons, Dr. Hayden mentioned a case that had a short time before fallen under his observation, and several others were cited by the author at the same time. Since then he has met with numerous cases in which this had occurred. It is doubtless the result of increased vascular action, excited in the lining membrane and pulp by the action of the arsenic, and it proves the capability of the vessels of teeth under certain circumstances, of conveying red blood. It occurs, however, much more frequently in the teeth of young, than in those of persons in advanced life.

kill. In other words, they *irritate* the parts beyond the dental cavity, and from this cause, (and perhaps from chemical injury to the tooth itself,) the periosteum of the root and socket becomes the seat of great, and frequently of uncontrollable difficulty. Entertaining these views, Dr. H. regards the use of such means, as opposed both to experience and sound philosophy, and adopts, without knowing that the same thing had been done by others, what he believes to be a more correct practice—immediate extirpation. He thus describes his method of procedure for the accomplishment of this object.

He says, “I first effect such an opening as will enable me to approach the exposed pulp, in the line of its axis, or as nearly so as circumstances will permit. Then, having carefully but sufficiently exposed the surface of the pulp, I pass down to the apex of the root, through the pulp, a small untempered steel instrument, with a trochar-shaped point, and revolving it once or twice, sever the vessel and nerve. This as any one knows, who is accustomed to inserting artificial teeth, produces but a slight and momentary pain. I then, by means of minute instruments, adapted to the purpose, endeavor to remove every portion of the severed pulp and lining membrane, and as soon as the hemorrhage ceases, dry the cavity and fill” the tooth.

In relation to the subsequent parts of the operation, Dr. H. says, “I have sometimes only filled the canals at the first sitting—leaving the body of the tooth to be treated after a few days. This course has been adopted from a fear that all the pressure necessary to complete the operation, might enhance the danger of inflammation and suppuration. This is prudent, but experience does not convince me that it is necessary.

“It should be borne in mind, that at the point where the vessels and nerve in question enter the root, the passage is much smaller than it is immediately within. This *strait* will be easily recognized when reached, by the touch, the instrument appearing to be arrested by an obstacle, and not

by being wedged in a narrow passage. Care should be taken, I think, that the instrument is not allowed to pass through the strait, either by being too small, or by being revolved there till it cuts its way through. For, by wounding the parts without the tooth, and forcing particles of bone out upon the parts external to the root, the danger of an unfavorable result would be greatly increased."

Dr. Harwood adds, in conclusion, that he believes it is better to make the division of the parts a little within the strait, though he does not regard the matter as being yet fully settled by observation and experience.

As to the success of the practice, Dr. H. speaks very confidently, not having had a case treated in this manner, where the patient and pulp were healthy, in which there has been a single symptom of alveolar abscess.

In a paper read before the American Society of Dental Surgeons, at the meeting held in the city of New York, August, 1845, and published in the sixth volume of the *American Journal of Dental Science*, p. 15, Dr. E. J. Dunning maintains very similar views with regard to the means most proper to be employed for the destruction of the pulp of a tooth. He says,

"The destruction of the nerve by mechanical means has been practiced to a small extent by dental surgeons for many years, but on account of the severe pain which in many cases attends it, as well as the fact that, in the manner in which it has generally been practiced, it has proved no more successful than other and less severe methods, it has been considered rather in the light of a *dernier resort*." But this, Dr. D. believes to be owing to the fact, that the nerve is often only punctured and lacerated, and afterwards shut up in the tooth and left to decompose. To prevent which, he says, the whole nerve should be removed, and its place filled with gold or tin foil.

Again, Dr. D. says, "The instrument which I have used to excavate the fangs, is a delicate probe of steel, perfectly annealed. The point may be converted into a very slight

hook, and made sharp, so as to bring away the nerve or other matter with which the cavity may be filled. For the removal of the nerve in the chamber of the crown, existing in molar teeth, as well as to enlarge the cavity, so as to give free access to each of the fangs, a burr-drill is very useful. As these teeth are generally very much decayed, it will be found advisable, when the cavity is on the side of the crown, to remove its edges in such a manner as to admit the light directly upon the openings of the fangs. This will facilitate the operation very much, and at the same time give strength to the walls that are to contain the stopping."

With regard to the result of the operation of filling the pulp-cavity and roots of a tooth in which the nerve has been destroyed in the manner as above described, Dr. Dunning says, so far as he has been able to observe, it has been successful in every case.

On the different methods of destroying the nerve, Dr. J. H. Foster, of New York, says, "It is a difficult matter, and I have generally found it utterly futile to attempt to induce patients to submit to the removal of the pulp by *extraction* or *excision* with *instruments*, in those cases in which it becomes necessary to destroy vitality before the teeth can be filled.

"To obtain the consent of the patient by a representation of the advantages of this mode of treatment, as contrasted with the more slow and uncertain practice, in its immediate effects, of *extirpation*, by the aid of *chemical agents*, has been my earnest endeavor. I do not remember a single case of the removal of the dental pulp by an instrument—the gold being inserted into the dental cavity immediately after the hemorrhage has been checked—which has resulted in alveolar abscess."

Dr. Foster, however, generally employs arsenious acid, with sulph. morphia, in the proportion of two grains of the former to eight of the latter, applied on a small pellet moistened with creosote. After applying this directly over

the nerve, he covers it with a cap, to avoid pressure ; then fills the external cavity with some soft material which will exclude moisture. At the end of forty-eight hours, he removes this, enlarges the dental cavity, removing its contents to the apex of the root ; then, after waiting another forty-eight hours, he proceeds to fill the canal, leaving the cavity in the crown to be filled at a subsequent sitting.

In performing this operation on molar teeth, "where there is a probable chance of a favorable issue," and the preservation of these teeth is particularly called for, he thinks it important that the excavation should be done at intervals, so as to cause as little irritation at each sitting as possible, and that the filling of the different cavities in the tooth be also proceeded with in like manner.

Dr. Maynard, who has been as successful in filling the pulp-cavity and roots of teeth as any other practitioner, and has probably had more experience, having been in the habit of performing the operation since 1838, having thoroughly tested the method of destroying the nerve by immediate extirpation with an instrument, as well as that by the application of arsenious acid, gives the preference to the latter. His method of procedure, as described in vol. 7, p. 286, of the American Journal of Dental Science, is as follows :* "He takes white wax and works it into cotton or lint, till it is thoroughly mixed together. With this he fills the cavity in the tooth." But, "before doing this, he exposes the nerve as much as possible, applies the arsenic, and *caps* the orifice with a plate of lead, of a cup shape, the convex side outwards. While this is carefully kept in place, he fills the cavity with the cotton and wax, very carefully and perfectly, in such a way as not to shut in and compress any air which might press upon the nerve. On removing this packing," in a case which the writer had an opportunity of witnessing, he says, "I was surprised to see that his preparation had been kept perfectly dry, although it had been there twenty-four hours.

* This is taken from an article by Dr. A. Westcott.

"After he removed this packing and the preparation, he proceeded to remove the nerve.. Instead of attempting to do this at once, he began by cutting on every side of the orifice, so much enlarging it as to be enabled to remove the nerve without pressing the contents of the cavity upwards.

"It was to us a matter of interest to examine the instruments used, particularly for removing the nerve.

"Some of his probes were made from the main-spring of a watch, by filing or grinding them sufficiently narrow, to enter the smallest space which he wished to probe. In this way he secures the most perfect *spring temper*, a point not easily attained in so frail an instrument as a probe adapted to this purpose. These probes were bearded by cutting them with a sharp knife—the beards pointing backwards. "With different sizes of these [and other] probes, and by enlarging the cavity from time to time, he removes the nerve to the extremity of the root.

The author of a series of ably written articles on the treatment of caries of the teeth, complicated with disorders of the pulp and peridental membrane,* published in the American Journal of Dental Science, recommends the use of cobalt for destroying the nerve as preferable to any other agent or means that have been employed for the purpose.

In the destruction of the pulp of a tooth the author has employed both mechanical and chemical agents. He has been in the habit of occasionally extirpating the nervous pulp to the extremity of the root by introducing a very small untempered instrument, with a spear-shaped point, for more than twenty years, though not at first with the view of afterwards filling the pulp cavity. He has also used the actual cautery and arsenious acid. To the use of the last named agent as used by most dentists for destroying the vitality of teeth, he was at one time strongly opposed, and he still believes a vast amount of injury is produced by it, but with proper care and judicious treatment after

* Dr. R. Arthur.

the destruction of the pulp, it may be used with safety, and, in most cases, advantage. It is the agent he now employs for destroying the vitality of the lining membrane and pulps of the molar and bicuspid teeth, and occasionally, he applies it to the incisors and cuspids. As a general rule, however, when he wishes to destroy the nerve of one of the last named teeth, he extirpates it by thrusting a small instrument up the pulp-cavity to the extremity of the root. When he uses arsenic, he applies about the thirtieth or fortieth part of a grain, with an equal quantity of sulphate of morphia, on a small particle of raw cotton, moistened with creosote, or spirit of camphor, sealing up the cavity with white or yellow wax. At the expiration of seven or eight hours, he removes the wax and arsenic, and afterwards the pulp of the tooth. If the portions in the roots are still sensitive, he applies it a second time, but he seldom finds it necessary to do so.

The method of procedure which he adopts in filling the root, or roots if it be a molar tooth, is the same as that pursued by Dr. Maynard, which has already been described.

"His operation," says the writer just quoted, "of filling the root, is characterized by the same neatness and dexterity. His instruments are of the most delicate kind, and are adapted to reach to the end of the fang, although the canal may not be entirely straight. In filling these roots," alluding to the operation which he says Dr. M. performed, he used very heavy gold, we believe from No. 12 to 30. This is cut into strips corresponding to the diameter of the cavity, and is not doubled. The end of one of the strips is laid upon the end of one of these delicate pluggers, and carefully carried up to the upper extremity of the root. If this is effected, the instrument is withdrawn a slight distance, then returned, carrying with it another portion, till the strip is exhausted. In this way the whole root is filled.

This part of the operation being completed, the cavity in the crown is filled in the usual manner.

It sometimes happens that the canals in the buccal roots

of the upper molars are so small as to preclude the introduction even of a small sized hog's bristle. In cases of this sort, it is impossible to fill them, and fortunately, from their small size, they cannot serve as reservoirs, for accumulations of morbid matter. The canal in the palatine fang is always much larger than in either of the buccal roots, and a majority of the cases is filled with comparative ease.

We have now presented a condensed summary of most of the information we possess in relation to the operation on which we are now treating; and notwithstanding the favorable light in which it is viewed by many eminent dentists, we think it should be restricted to teeth, the presence of which in the mouth, is called for by some *peculiar* or *urgent* necessity. It is only in *such cases*, that we conceive the operation to be advisable; for the unsuccessful results which have, at least occasionally, attended it, in the practice of every one, who has performed it many times, prove that a tooth, after the destruction of even the lining membrane and pulp, is more liable to give rise to a diseased action in the socket, than a tooth not deprived of these essential constituents. If these parts did not perform some necessary function, or contribute in some way to the well being of the tooth, or the parts with which it is connected, they would not be left there; the process of dentinification would doubtless be carried on until the cavity in which they are contained was completely obliterated. Still, these parts, as we have already stated, and as is fully proved by the facts which have been adduced, may often be dispensed with without causing a tooth to exercise any *immediate manifest* hurtful action upon the surrounding parts or general system.

It sometimes happens that the crown of a tooth, in which the central cavity has been filled for a length of time with black purulent matter, or the pulp after having been accidentally deprived of vitality by the application of arsenic to a carious cavity, with a view of merely destroying sensibility, assume a dark brown, and sometimes almost a black color. This, in some cases, extends to every part of the dentine of

the crown, and in such cases it is important to restore the natural color of the organ, before filling. The agent which the author has employed for this purpose, for a number of years, is a solution of the chloride of soda. After freeing the pulp-cavity to the extremity of the root of all impurities, and removing from its inner walls, the softened or decomposed portions of dentine, he fills the tooth with raw cotton, saturated with this solution, closing the orifice with white wax, and permitting the whole to remain for twenty-four hours. A single application will sometimes produce the desired effect; at other times several are necessary. Dr. Dwinelle has used successfully, for the same purpose, a solution of lime.

CHAPTER SEVENTH.

FILLING TEETH WITH CRYSTALLINE AND SPONGE GOLD.

Two preparations of gold for filling teeth, each differing somewhat in appearance, and to some extent in properties, from the other, and both from foil or leaf gold, have within the last few years been brought to the notice of the dental profession. Each has a spongy texture and appearance, but one is composed of crystals, and the other of small granular particles. The former is reduced more readily, by pressure, into a solid mass, than the latter, and hence has been found better adapted to the operation of filling teeth. But in the use of either of these preparations, a different method of procedure is required from that employed with foil; and the instruments necessary to make a filling with the one, are, in many cases, unsuited to the operation with the other. A separate description of the system of manipulation, therefore, is deemed necessary.

INSTRUMENTS EMPLOYED IN THE OPERATION.

The chief difference between the instruments employed for introducing these preparations of gold into the cavity of a tooth, and consolidating them, from those used for foil, consists mainly in having the working extremity blunt, but varying in diameter from a line down to nearly a sharp point, with cross cuts upon the surface, giving it a sharp denticulated appearance. Some original forms of instruments have, however, been invented, but most of those used

at present are mere modifications of instruments heretofore employed for filling teeth with gold-foil.*

In Fig. 109 is seen a representation of an instrument with a round point, flat on one side and slightly convex on the other, designed, chiefly, for carrying small masses of crystalline or sponge gold to, and pressing them in, the orifice of the cavity of the tooth to be filled, or to place them upon that previously introduced. It is a convenient and useful instrument, and cannot well be dispensed with in working these preparations of gold. Several sizes are required.†

FIG. 109.

An instrument somewhat similar to the foregoing is represented in Fig. 110. The point, instead of being round or circular, is oval, bent to a greater angle, with a slight oval on each side. It is intended more particularly for carrying small masses of crystalline or sponge gold to, and pressing them in, the orifices of cavities in the approximal surfaces of teeth slightly separated from each other. It is better adapted for this purpose than any instrument at present used.

FIG. 110.

The surfaces of the working extremities of both of the foregoing instruments, as indeed are all that are used for filling teeth with these preparations of gold, are cross cut, forming upon them numerous fine sharp points. Several sizes of the one last as well as the one first described are needed.

FIG. 111. FIG. 112. FIG. 113.

* A series of the most approved forms that have been gotten up for the purpose, are represented in an article by Dr. W. H. Dwinelle, published in the April No. of Vol. 5, New Series, of the American Journal of Dental Science. Most of the cuts in this chapter are copied from them.

† The instruments represented in Fig. 109, are from patterns gotten up Dr. Wm. M. Hunter, of Cincinnati, Ohio.

In Fig. 111 is seen a representation of an instrument slightly bent at the working extremity—the upper surface of which is flat, and terminates in a blunt point. It is designed chiefly for introducing and compressing the gold in the grinding surface of molar teeth, both of the upper and lower jaws. Fig. 112 represents an instrument having the general form of the one last described, but filed out on the under surface, as shown in the cut; the point, being prominent, is intended to be introduced a short distance into cavities in the posterior approximal surface of molar and bicuspid teeth. It is one which may be advantageously employed in many cases. Several sizes, however, both of this and the preceding one, are required, with slight modifications of form. The instrument represented in Fig. 113, is designed for introducing gold in cavities in the approximal surfaces of incisor and cuspid teeth, and for which purpose it is peculiarly adapted.

FIG. 114. FIG. 115.

The instruments represented in Fig. 114, are said to be very useful in filling cavities in the approximal surfaces of teeth, and judging from their appearance, we have no doubt they may be very advantageously used in many cases.* The instrument represented in Fig. 115, and of which several are required, varying in size and bent at different angles, is chiefly employed in filling cavities in the approximal surfaces. The working extremity is serrated.

FIG. 116.

FIG. 117.

Instruments with their working extremities bent to various angles, and of different lengths and sizes, some reduced nearly to a sharp point, like those represented in Fig. 116, are required in consolidating

* These instruments were gotten up by Professor Arthur.

the gold in cavities of the grinding, approximal and buccal surfaces. The points may be round or flat, as may suit the fancy of the operator. A description of an instrument, like the one represented in Fig. 117, will also be found very useful in condensing. Points, however, much smaller than the smallest here represented, bent to several different angles, are needed.

The instruments shown in Fig. 118, are used for introducing and partially compressing gold in approximal cavities. The working extremities, as seen in the cut, forming a right angle with the stem of the instrument, should vary in length and diameter, from the largest here figured, to the most delicate dimensions, to be made available in the various cases in which their use may be required.

FIG. 118.

An instrument with working points somewhat like those shown in Fig. 118, with the stem bent to a lateral angle, a short distance above the serrated extremity, is represented in Fig. 119. When bent in this way, they are made in pairs, one for the right and one for the left side, and as with the instruments before described, they should vary in size.

FIG. 119.

For introducing and partially condensing gold in approximal cavities in the oral and bicuspid teeth, they are peculiarly well adapted. The author has a set made from patterns gotten up by Dr. Ballard, of New York, which, for this purpose, he has found more serviceable than any other description of instrument.

FIG. 120.

The instruments in Fig. 120 are used in introducing and partially compressing gold in ante-

rior and posterior approximal cavities of molar and bicuspid teeth; but instruments of this description have been used by dentists for many years for condensing gold foil, but they may be employed more advantageously in working crystalline gold. It is only, however, in the earlier stages of the operation that they can be very efficiently used, unless the working extremity be very small.

FIG. 121.

In Fig. 121, instruments with variously shaped points are represented. Some of them are mere modifications of a few of those previously described. But in the use of crystalline and sponge gold, they will all be found very useful.

FIG. 122.

The instruments represented in Fig. 122, are some the author had constructed for partially condensing the angles around the grinding surface of a tooth, when he finds it is necessary to build up the whole or part of the crown. With instruments like these, the particles of gold are pressed together and partially united, the side and grinding surface being both acted upon at the same time; smaller points may be afterwards applied, without danger of crumbling the mass thus built up. For purposes of this sort, instruments like these are very useful.

Other forms of instruments are sometimes employed in the use of sponge gold, but one-fourth of those even here represented will be found amply sufficient for most operations, and hence it has not been deemed necessary to give a more extended description.

INTRODUCING AND CONSOLIDATING THE GOLD.

In filling teeth with crystalline or sponge gold, the cavity in the tooth is prepared in the manner as described when leaf gold is employed. This done, the gold is cut into small pieces, varying in size according to the dimensions of the cavity and the particular stage of the operation in which it is to be used. It being important that the crystals or particles composing the mass, should be as little separated or displaced as possible, before the piece is carried to its place in the tooth; it should be used in as large pellets as can be introduced into the cavity without crumbling.

The gold being cut into pieces of the proper size, the cavity is washed, and then wiped dry with prepared raw cotton or spongy tissue paper, a piece of gold, as large as the orifice of the cavity will receive, is placed over it with suitable pliers or one of the instruments represented in Fig. 109, or Fig. 110, as may be most convenient, which is well adapted to the purpose—the spongy mass readily adhering to the serrated surface of the working extremity, when pressed gently upon it, and with which it may also, in most cases, be carried to the bottom. Every part is now thoroughly consolidated, first with a large, and next with a smaller, and lastly with a very delicate-pointed instrument, so bent that it may be readily applied to all the depressions and inequalities of the walls and floor of the cavity; for unless the gold is made absolutely solid in these places, as well as throughout all the parts of the filling, the success of the operation will be more or less uncertain. Thus, piece after piece is applied, consolidating each one as the operation progresses, until the gold protrudes sufficiently from the orifice of the cavity to admit of a good finish, leaving the surface flush with the surface of the tooth.

If, during any part of the operation, the smaller pointed instruments can be forced between the gold and the walls of the cavity, such opening or openings, if more than one is made, should be filled with smaller masses of the material

before another large one is introduced. This precaution ought never to be neglected, for should any soft places exist after the completion of the operation, the filling will be liable to absorb moisture and ultimately to crumble and come out. It is also necessary, as we have before stated, that the gold, during the introduction of it into the tooth, be kept absolutely free from moisture, as this destroys the welding or uniting properties of the crystals.

The gold having been introduced and consolidated as directed, the exposed surface is scraped or filed down to a level with the orifice of the cavity, then made smooth by rubbing it with Arkansas rock or oil stone, or with finely powdered pumice, and burnished or polished with crocus, in the manner as described when gold foil is used.

In finishing a filling made with these preparations of gold, the operator should see that there are no thin overlapping portions upon the teeth outside of the orifice of the cavity, as they are liable, in biting hard substances, or in mastication, to be broken off, leaving a depression to serve as a lodgment for extraneous matter and clammy secretions, which, sooner or later, according to the density of the tooth, will give rise to a softening of the dentine thus exposed, which, if it does not cause the filling to loosen, will ultimately render its removal and the replacement of it necessary. In short, the precautions necessary to be observed in making a filling with gold foil should be as carefully attended to when the operation is made with either of the preparations now under consideration.

We might enlarge upon this part of our subject, by going into detail and describing the various manipulations required to fill a tooth in the several localities in which the operation may be called for, but the foregoing general directions, it is believed, will serve as a sufficient guide to the dentist in the use of these preparations of gold.*

* For a fuller exposition of the subject, the reader is referred to a series of interesting articles by Dr. C. W. Ballard, published in the March, April, May and June numbers for 1855, of the New York Dental Recorder, and to the article previously referred to by Dr. Dwinelle.

CHAPTER EIGHTH.

BUILDING ON THE WHOLE OR PART OF THE CROWN OF A TOOTH.

FEW persons have the patience to undergo an operation requiring as much time for its performance, as the building on of the whole, or a large part of the crown of a tooth, and fewer still, are willing to incur the expense of the labor and gold necessary to make one. Hence, it is seldom attempted, and can only be performed by the most expert and skillful manipulators. Nevertheless, as it is sometimes made, it would not be proper to omit a description of the manner of doing it. It is scarcely to be expected however, that any one who has not had considerable experience in filling teeth, and acquired a high degree of dexterity in the use of instruments and the working of some one or more of the preparations of gold employed for the purpose, will, simply from any directions that can be laid down upon the subject, be able, at once, to make the operation. But it is hoped, that the following description may serve as a guide to those who have never attempted it and may wish to exercise their mechanical and artistic abilities on the most difficult of all operations in dentistry. Those only who are aiming at high excellence in this department of practice, will be likely to undertake it, and should their first efforts prove unsuccessful, the increase of skill they will have thus acquired in the use of instruments, will inspire new confidence, and ultimately, by perseverance, enable them to achieve the object of their wishes.

The operation to be successful must not only be performed in the most perfect manner but the tooth also must be

situated in a healthy socket and firmly articulated. Under other circumstances it would be useless to attempt the restoration of the organ. The general system too, should be free from preternatural susceptibility to morbid impressions.

A tooth on which the operation is called for, has, in nearly every case, suffered so much loss of substance as to involve exposure of the pulp, and consequently the destruction and removal of this, is the first thing to be attended to, unless as is sometimes the case, it has previously perished from inflammation and suppuration. When this has happened, the permanent preservation of the organ cannot be counted on with as much certainty as when it is destroyed by the application of an escharotic two or three days before the performance of the operation. Its destruction by the suppurative process is more apt to be followed by alveolar abscess, and this having once established itself, is seldom so completely cured as to prevent the liability of its recurrence. But if the operation is still determined on, the parts at the extremity of the root, must first be restored to health, and failing to accomplish this, it should not be attempted. The treatment in cases of this sort, as well as of simple morbid secretion escaping from the fang, is described in another chapter.

In describing the operation we will commence with the first molar of the left side of the superior maxillary. We will suppose that about three-fourths of the crown has been destroyed by caries, and that the buccal wall is the only portion remaining, the nervous pulp being more or less exposed. This is destroyed and extirpated to the extremity of each root in the manner as described in another place. The decayed portions of the tooth are now removed, and the central chamber enlarged until the wall of dentine on the palatine, anterior and posterior approximal sides are only about one line in thickness. On the inside of this wall, a shallow groove or undercut is made to give additional security to the gold.

The tooth as now prepared is represented in Fig. 123,

and having proceeded thus far with the operation, the introduction and building on of the gold may be commenced. But before describing the manner of doing this, it may be well to say a few words with regard to the preparation of gold most proper to be employed. For filling the roots, the foil ordinarily used is the best. If the leaves are thick, weighing from fifteen to twenty grains, it should be introduced in very narrow strips, without folding, in the manner as described in another chapter ; if leaves of four or six grains are preferred, it may be cut in strips varying from an eighth to a quarter of an inch in width, according to the size of the canal in the root, and then made into very narrow folds, or rolled before using. For the central chamber and crown, gold possessing adhesive properties should be employed, and this property may be imparted to common gold foil by slightly annealing immediately before using ; but foil made from crystalline gold possesses it in a higher degree, and this also requires to be annealed. Either kind of foil, therefore, or crystalline gold, may be employed. The operation, however, can be made with less labor with either of the two first than with the last named preparation.

FIG. 123.

The manner of filling roots having been described in a preceding part of this work, we shall commence the operation with the pulp-cavity. The gold, supposing it to be foil, is cut, each leaf of No. 4 into from four to six pieces, which are loosely rolled into round or oval pellets. A sufficient number of these having been prepared, the surfaces against which the gold is to be placed are made perfectly dry by wiping with tissue or bibulous paper, or raw cotton. This done, one of the pellets or balls is placed in the central chamber with pliers, and partially consolidated with a small pointed integrating instrument, another and another is added, each being consolidated as the first, until a sufficient number have been introduced to obtain the necessary mechanical support from the surrounding wall of dentine to prevent any

portion from being moved from the place it is first made to occupy. The process of consolidation is now repeated and continued until no part of the gold can be made to yield to the pressure of the instrument, when additional pellets are applied and condensed as in the first instance, until the pulp-cavity is completely filled, forcing those placed against the surrounding wall firmly and compactly into the groove or undercut made in it, thus securing for the entire mass the greatest possible stability. Again, pellet after pellet is applied, pressing those placed along the outer edge of the gold already occupying the central chamber firmly against the exposed margin of dentine and the buccal wall of the tooth, until a solid mass, considerably larger than the portion of the crown to be supplied shall have been thus formed.

For the complete solidification of every part of the gold, and the welding of every piece—the one to the other, a number of instruments are required, with integrating points, varying in size from the one represented in Fig. 99 to less than half the size of the one in Fig. 96. For some portions of the operation a straight instrument can be employed most advantageously; for other parts one slightly bent near the point, and for others one bent to a right angle with the stem. But the kind that can be most efficiently used must, after all, be determined by the judgment of the operator. One, perhaps, may use very efficiently an instrument in a particular locality and for a certain purpose, that another for the same purpose would handle very awkwardly. But for completing the work of consolidating, all agree that very small pointed instruments are indispensable.

As the adhesiveness of the gold is destroyed by the contact of liquids, it must be kept absolutely free from moisture during the entire process of applying and consolidating the metal. But if, notwithstanding all the precaution the dentist is able to use, the saliva should come in contact with the operation before this part of it is completed, the gold which has already been applied must be thoroughly

consolidated, then dried with bibulous paper or some other good absorbing substance, the surface scraped, burnished, dried again, and made rough with a sharp-pointed instrument—one like those used by engravers will be found best adapted to the purpose. To this surface other portions of gold may be united, and the operation from this point carried on to completion.

Having arrived at this stage of the operation, the next thing to be done is to consolidate thoroughly every part of the surface. This may be commenced with the larger pointed integrating instruments. After going over it ten or a dozen times with these, smaller points may be used, and these again changed for still smaller, and so on until no appreciable impression can be made upon any part of the gold.

It now remains to file and scrape the surface until the gold is made to assume very nearly the shape of that portion of the original tooth, the loss of which it supplies. In doing this an opportunity is afforded the operator of displaying his artistic skill and ingenuity—his ability, in short, to copy nature. While shaping the grinding surface, the patient should be requested from time to time to close his mouth, that the depressions in it may be made of the proper size and shape for the reception of the protuberances of the tooth with which it antagonizes, that these two may touch at the same instant the other teeth of the upper and lower jaws come together. This part of the operation is always tedious, usually requiring more time than for the consolidation of the gold.

The operation being reduced to the required size and form, the surface of the gold may be rubbed with properly shaped pieces of Arkansas or Lake Superior rock, or finely pulverized pumice, until all the scratches left by the file are removed. It is then polished with crocus or a burnisher. The appearance of the tooth as now restored may be seen in Fig. 124.

FIG. 124.

As it is impossible to perform the entire operation at

one time, it may readily be divided into three parts. The *first* may consist in the extirpation of the nervous pulp and the preparation of the tooth ; the *second*, in the application and solidification of the gold ; the *third*, in giving to the metal the proper conformation and finishing the surface. The time required for the first, supposing the operation to be like the one just described, may vary from one and a half to two and a half hours ; for the second, from two to three and a half hours, and for the third, from two to six hours, according to the difficulties that may be encountered during the progress of its performance, the ability of the dentist, and the completeness of his preparation for it.

Some, perhaps, may prefer crystalline or spongy gold, supposing the crystals or granules are more easily united, one to another, than the surfaces of adhesive foil ; but as the manner of working these preparations has already been described, it will not be necessary to give additional directions upon the subject. The operation of building on the crown or part of the crown of a tooth, should, for the most part, be proceeded with in the same way with the one as with the other. If too large a piece of either is used at one time, the surface will become crusted over by the pressure of the point of the instrument, and prevent, by any subsequent force that can be safely applied, its thorough consolidation. In this case, the general mass will be more or less spongy and the operation imperfect. The dentist should be well assured, therefore, as he progresses with his work, that every part is executed in the most thorough and perfect manner.

As the same system of manipulation is practiced in building on the entire crown of a tooth as in the operation just described, it will not be necessary to recapitulate what has already been said upon the subject. A dentist who can do one, can also do the other. The only difference is in the time occupied in making the respective operations. The first, of course, requires more than the second.

A large portion of the crown of a tooth may be built up

with ordinary gold-foil, if it be of the best quality; but the adhesive preparations, whether in leaf or in the crystalline or spongy form, are preferable.

It is more difficult to build on the crown of a tooth in the lower than in the upper jaw, owing to the increased liability of the locality to be encroached upon by the fluids of the mouth.

We have endeavored, in the foregoing description, to point out the general method of procedure in the operation on which we have been treating. We have also noticed some of the precautions necessary to be observed—but unexpected difficulties are sometimes encountered—the peculiar nature of which it is impossible, *a priori*, to describe. Few, however, are of so formidable a character that they cannot be overcome.

CHAPTER NINTH.

TOOTH-ACHE.

PAIN in a tooth, tooth-ache, or *odontalgia*, as it is technically termed, is a symptom of some functional or structural disturbance, either of the organ in which the pain is seated, or of some other part or parts of the body; but more frequently of the former than of the latter. But so variable is the character of the sensation, that any description would fail to convey, to one who has never experienced it, a correct idea of its nature. The pain sometimes only amounts to slight uneasiness; at other times the agony is almost insupportable. It may be dull, deep seated, boring, throbbing, or lancinating. It may be slight at first, gradually increasing in severity until it amounts to the most excruciating torture, or it may come on without any premonition whatever. It may be confined to a single tooth, or it may affect several at the same time. It may commence in one tooth, and pass from thence to another, and continue until every one in turn has been attacked. It may continue for hours and days without scarcely any cessation, or it may be intermittent, the paroxysms recurring at stated or uncertain intervals, and each lasting from thirty minutes to one, two, or more hours.

CAUSES.

The causes of tooth-ache are almost as numerous as are the varieties of character which it exhibits. Irritation and inflammation of the pulp, and inflammation of the investing membrane are among the most frequent, but it is sometimes referable to a morbid condition of the nerve or

nerves going to a single tooth, or of "the trunk from which several teeth are supplied," also, to derangement of the digestive organs, to increased nervous susceptibility of the uterus resulting from pregnancy, amenorrhœa, &c., and to certain diatheses of the general system.

Dr. S. P. Hullihen enumerates the following as the causes of tooth-ache; 1, exposure of the nerve; 2, fungus of the nerve; 3, confinement of pus in the internal cavity; 4, a diseased state of the periosteum covering the fang, and 5, sympathy.* Dr. Heilden attributes it to congestion or inflammation, or a leison of innervation of the lining membrane and pulp, or of the peridental membrane.†

Inflammation of the lining membrane and pulp, may be produced by a blow upon a tooth, or by powerful impressions of heat and cold communicated through the conducting medium either of the enamel and dentine or of a metallic filling; but it is more frequently occasioned by pressure and the direct contact of irritating agents, such as carious portions of the tooth, particles of alimentary substances, acrid humors and other irritating external bodies. But inflammation is not always a necessary consequence of impressions of this sort. Pain may be produced by them when it does not exist, but in this case it usually subsides soon after the removal of the irritant. Indeed the pulp of a tooth may be exposed for months, and subjected several times every day to the contact of foreign substances, without becoming the seat of inflammatory action, and in the absence of which, the pain, though coming on with the suddenness of an electric flash, and often of the most excruciating kind, is seldom of long duration.

But when inflammation exists, the pain, which at first, amounts only to a slight gnawing sensation, is more constant; after a while, it assumes a throbbing character, and if not promptly arrested, it increases in severity and continues until suppuration of the lining membrane and pulp

* American Journal of Dental Science, vol. i, p. 106.

† Half-yearly Abstract of Medical Science, vol. i, 1845.

takes place. So long as it is confined to the parts within the pulp-cavity, the pain is not increased by pressure on the tooth, nor is the tooth started from the socket, as it is in periodontitis. The locality of the inflammation may also be distinguished by the fact, that cold water or ice applied to the tooth, generally gives relief. But the inflammation rarely confines itself long to the interior of the tooth; it usually soon extends to the periosteum of the root, and alveolus, when a somewhat different train of phenomena are developed. Suppuration, however, having taken place, an abscess soon forms at the extremity of the root.

The severity of the pain attending *odontitis*, as inflammation of the pulp is technically termed, from the supposition that every part of the organ is involved in the diseased action, is, doubtless, owing to the fact that this exceedingly sensitive structure, as its vessels become injected with blood, is prevented from expanding by the unyielding nature of the walls of the cavity in which it is situated. Its capillaries being thus distended, must as a necessary consequence, press upon the nerves which are everywhere distributed upon it, and the excruciatingly painful throbbing sensation by which this variety of tooth-ache is characterized, is produced, we have no doubt, by the pulsation of these vessels which takes place at each injection from the artery supplying them with blood. Hence, increased action of the heart and arteries, from whatever cause produced, augments the pain, which is also more severe at night, while the body is in a recumbent posture, than during the day. The phenomena attending the inflammation, however, are influenced very much by the condition of the tooth and the habit of body of the patient.

When the inflammation is acute, it extends to every part of the pulp and lining membrane. It also occurs more frequently before than after these tissues have become exposed, and generally terminates in suppuration. Chronic inflammation usually arises from partial exposure of the pulp, and may exist for months without being attended with pain; but

the pulp, when thus effected, is more susceptible to impressions of heat and cold, and of irritating substances, and the liability of the tooth to ache, especially at night, is greatly increased.

Tooth-ache caused by acute inflammation of the investing membrane, is characterized by pain, at first dull, afterwards acute and throbbing, soreness and elongation of the tooth, redness and tumefaction of the gums, and sometimes by swelling of the cheek, indicating the formation of alveolar abscess. In this variety of odontalgia, the tooth is often so much raised in its socket as to interfere more or less with mastication.

The pain attending the foregoing pathological conditions, when severe and protracted, is often accompanied by constipation, head-ache, dryness of the skin, flushed cheeks, fullness and increased rapidity of pulse, and other constitutional morbid phenomena.

The nervous susceptibility of the teeth is sometimes so much increased by organic and even functional disturbances of other and often remote parts, that the mere contact of the minute nerves, distributed upon the pulp, the lining and investing membranes, with the parts with which they are associated, is frequently attended with severe pain. This variety of odontalgia is termed *sympathetic*, and is supposed to be the result of the transfer of nervous irritation, or more properly, we would suppose, of *exalted excitability* of the dental nerves, arising from a morbid condition or functional disturbance of some other part. If this hypothesis be true, it is probable, that with this heightened nervous excitability, there is a slight increase of vascular action in the pulp, the lining and investing membranes of the tooth, with a corresponding increase of size in their capillaries, and in consequence of which, it is fair to presume, they would be likely to exert some undue pressure upon the nervous filaments supplying these tissues. Though pain, arising from this cause, may have its seat in sound, as well

as in decayed teeth, it occurs more frequently in the latter than the former, owing to the fact that any structural alteration in the dentine, adds to their already increased nervous excitability.

Persons of highly excitable nervous temperaments, pregnant females, and individuals laboring under a deranged condition of the digestive organs are particularly subject to this variety of tooth-ache. It also sometimes occurs as a symptom of rheumatism or gout,* the pain in cases of this sort, assuming the specific character of that which characterizes these diseases. Odontalgia arising from other pathological conditions or functional disturbances of other parts, assumes a great variety of forms. The pain may be continued, but more frequently it is periodical. It may be confined, as we have before stated, to a single tooth, or it may attack half a dozen or more at the same time, the pain assuming every variety of grade and character.

In what is termed neuralgic tooth-ache, "the pain," says Dr. Wood, "is usually of the acute character, sometimes mild in the beginning, gradually increasing in intensity,

* A most remarkable and interesting case of tooth-ache, associated with gout, fell under the observation of the author, in May, 1850. The subject, Mr. W., a resident of Baltimore, about forty years of age, had been subject to attacks of this most excruciatingly painful affection, for more than fifteen years. The paroxysms, for some four or five years previously to the above mentioned time, had occurred at intervals of from three to six months, and from ten to twelve days before each attack, during this period, he suffered from pain in the first right superior molar tooth, which was slightly affected with caries in the centre of the grinding surface, but it had not yet penetrated to the pulp-cavity. The pain at first was not severe, but it gradually increased in intensity, and assumed a peculiar boring, and at times, grinding and lancinating character. His attacks of gout were confined to the joint of the big toe of his right foot, and as soon as the pain commenced here, it subsided in his tooth. But when the paroxysm of gout began to pass off, it again commenced in the tooth, where it continued for about two weeks.

At the request of Mr. W., we removed the diseased portion of the tooth and filled the cavity. The operation for about three months promised to be successful, but about ten days previously to the next paroxysm of gout, the tooth began to ache, the pain subsiding with the occurrence of the paroxysm, but commencing again when it had passed off, and continued as it had formerly done for about two weeks. His suffering from the pain in the tooth during these periods was so great that he determined to have it extracted. The operation was successful.

and as gradually declining; but usually very irregular, at one time moderate, at another severe, and occasionally darting with excruciating violence through the dental arches. Not unfrequently it assumes a regular intermittent form. Instead of pain, strictly speaking, the sensation is sometimes of that kind which is indicated when we say that the teeth are on edge, and is apt to be excited by certain harsh sounds, such as that produced in the filing of saw teeth, by mental inquietude, and by the contact of acids or other irritant substances. Neuralgic tooth-ache sometimes persists, with intervals of exemption, for a great length of time. The diagnosis is occasionally difficult. When, however, it occurs in sound teeth, it is paroxysmal in its character, is attended with little or no swelling of the external parts, occupies a considerable portion of the jaw, and especially when it alternates or is associated with pain of the same character in other parts of the face, there can be little doubt as to its real nature." This is a variety of sympathetic tooth-ache, favored, perhaps, by caries, or by the manner in which the teeth are arranged in the alveolar arch, or by some peculiar susceptibility of the parts to morbid impressions, as is shown by the fact, that the pain almost always ceases on the removal of all causes of irritation. But while, on the other hand, pain in the teeth may be caused by a morbid condition of other parts, other organs frequently sympathise with the diseased condition of these, and become, to use the language of Mr. Bell, "the apparent seat of pain." "I have," says this writer, "seen this occur not only in the face, over the scalp, in the ear, or underneath the lower jaw, but down the neck, over the shoulder, and along the whole length of the arm." Cases of this sort are frequently met with.

In treating of tooth-ache, Dr. Good observes: "This is often an idiopathic affection, dependent upon a peculiar irritability, from a cause we cannot easily trace, of the nerves subservient to the aching tooth, or the tunics by which it is covered, or the periosteum, or the fine membrane

that lines the interior of the alveoli. But it is more frequently a disease of sympathy, produced by pregnancy, or chronic rheumatism, or acrimony in the stomach, in persons of an irritable habit."

"It is still less to be wondered at, that the nerves of the teeth should often associate in the maddening pain of *neuralgia faciei*, or tic douloureux, as the French writers have quaintly denominated it, for here the connection is both direct and immediate. In consequence of this, the patient, in most instances, regards the teeth themselves as the salient points of pain, (*and they unquestionably may be so in some cases,*) and rests his only hope of relief upon extraction; and when he has applied to the operator, he is at a loss to fix upon any one point in particular. Mr. Fox gives a striking example of this, in a person from whom he extracted a stump which afforded little or no relief; in consequence of which his patient applied to him only two days afterwards and requested the removal of several adjoining teeth, which were perfectly sound. This he objected to, and suspecting the real nature of the disease, he immediately took him to Mr. (now Sir) Astley Cooper, who, by dividing the affected nerve, produced a radical cure in a few days."

The author is acquainted with a gentleman similarly affected. He has had all his teeth on the right side of both jaws extracted, without obtaining any relief.

There is still another cause of tooth-ache, which we should not omit to mention; namely, exostosis; but from the obscurity of the diagnosis, the existence of the affection can seldom be determined with positive certainty, except by the removal of the tooth. But as we shall hereafter have occasion to treat of this disease, it will not be necessary in this place, to enlarge upon the subject.

Finally, some teeth, from peculiar constitutional idiosyncrasy, are more liable to ache than others. It sometimes happens that every tooth in the mouth is destroyed by caries without being affected with pain, while at other

times, teeth apparently sound become the seat of the most agonizing torture.

T R E A T M E N T .

The first thing to be attended to in the treatment of tooth-ache, is the removal of the causes which have given rise to it, and this can only be done by carrying out the curative and remedial indications of the morbid conditions and functional disturbances with which it is connected. While these continue, it will be impossible to obtain permanent exemption from pain. The sensibility of the nerves supplying a tooth may often be obtunded, and the pain palliated by the application of stimulating and anodyne agents to the exposed pulp, but the relief thus procured is seldom of long duration. When their effects subside, the pain usually returns with increased severity. When the pain arises from chronic inflammation and irritation produced by external agents on an exposed portion of the lining membrane, applications of this sort may sometimes be employed with great advantage; and among those which have been used for this purpose are creosote, the oil of cloves, cinnamon, cajeput, etc., laudanum, spirit of camphor, tannin, ether and chloroform. But of the preparations prescribed by the author, he has found none more useful in allaying the pain than the following :

R Sul. ether,	℥ i.	R Sul. ether,	℥ i.
Pul. camph.	℥ ij.	Creosote,	℥ ss.
Pul. alum,	℥ ij.	Ext. nut galls.	℥ i.
Sul. morphia,	℥ i	Misce. Pul. camph.	℥ ss. Misce.

After removing all foreign matter from, and carefully drying, the cavity of the tooth, a small bit of raw cotton or lint dipped in either of the above may be applied, and renewed several times a day if necessary. The relief obtained by the application of the above preparations, is in

he majority of cases, almost instantaneous, but as the effect is only temporary, a recurrence of the pain is liable to take place. The author has sometimes used, a thick solution of *gutta percha* in chloroform. The application of a drop or two of this to the exposed pulp is usually followed by immediate cessation of pain, and as the chloroform evaporates, a thin layer of *gutta percha* remains and serves for a time as a sort of protection to the pulp.

But the only way in which permanent exemption from pain can be procured, is, by the extraction of the tooth or the destruction of the pulp, and as there are many cases in which the patient cannot be prevailed upon to submit to the former, and as there are others in which the retention of the organ is called for by some peculiar necessity, it often becomes necessary to have recourse to the latter. This may be effected either by immediate extirpation with a small sharp-pointed elastic stilet or probe, the actual cautery, arsenious acid,* cobalt, or chloride of zinc. But immediate extirpation, arsenic or cobalt are the means usually employed for the purpose, and as we have described the manner in which the destruction of the pulp is effected by each of these, it will not be necessary to say anything here upon the subject.†

Pain in a tooth arising from acute inflammation of the pulp and lining membrane, can only be removed by the extraction of the tooth, the destruction of the pulp, or by subduing the inflammatory action, and the last can seldom be done except in its very incipency, and then, only, by the most energetic treatment, in cases where the decay has not penetrated to the pulp-cavity. The propriety or impropriety of extraction will be determined by the amount of pain, the progress made by the inflammation, the condition of the

* The employment of arsenious acid for the destruction of an exposed dental pulp, and the relief of the pain arising therefrom, originated with the late Dr. Spooner of Montreal, and in 1835, it was recommended to the profession by his brother, Dr. S. Spooner of New York, in an excellent popular treatise upon the teeth.

† See Filling the Pulp-cavities and Roots of Teeth.

parts with which the tooth is immediately connected, the effect of the local disturbance upon the general system, the situation and importance of the tooth, and the extent of structural alteration which has taken place in the crown. If the retention of it, on account of its location, or the loss of several other teeth, is of great importance to the patient, and the circumstances of the case justify a well-grounded belief that it can be preserved and rendered useful, without acting as a morbid irritant, the operation, if possible, should be avoided. In this case, supposing the inflammation to have proceeded too far to be arrested, the pulp may be destroyed and the tooth treated in the manner as described in another chapter, as it would be useless to procrastinate the suffering of the patient by instituting other treatment in the vain hope of avoiding an alternative, which, after all, may not enable the dentist to secure the permanent preservation of the organ. Indeed after the lining membrane has become exposed, this is the only method of procedure, in any stage of the inflammation, which, with a view to the preservation of the tooth, holds out any prospect of success.

When the inflammation is produced by other causes than exposure of the pulp and contact of external irritants, it may be, sometimes, successfully combated. The treatment in cases of this sort, is similar to that for local inflammation in other parts of the body, and should consist of saline cathartics, leeches to the gum of the affected tooth, abstinence from animal food and stimulating drinks. If the pulse is full and hard, blood may be taken from the arm with advantage. If these means fail to arrest it, and the inflammation be permitted to continue until suppuration takes place, the formation of alveolar abscess may be prevented by promptly perforating the crown of the tooth for the escape of the matter, but when it has this termination, it usually gives rise to periodontitis, which, perhaps, arise as frequently from this as any other cause.

The treatment of inflammation of the investing membrane is, for the most part, the same as above. But, in addition

to which, the mouth may be gargled several times a day, with some cooling astringent wash. Fomentations to the face and plasters of the seeds of hyoscyamus, mustard, capicum, or other narcotic or rubefacient applications have sometimes been found useful. But when the formation of alveolar abscess is threatened, the removal of the tooth, in most cases, will be found necessary. If it be an incisor or cuspidatus, however, the operation should only be performed as a last resort. When the inflammation is chronic, the necessity for the removal of the tooth is still more urgent.

Tooth-ache assuming a rheumatic or gouty form often calls for a somewhat different plan of treatment. In addition to the local means already described, it may be necessary to adopt the constitutional treatment applicable for rheumatism and gout. When the pain arises from increased vascular action and nervous irritation of the pulp, occasioned by a disordered condition of the digestive organs, and assumes an intermitten form, an emetic or cathartic, followed by the use of quinine, will generally afford relief, provided caries has not penetrated to the pulp-cavity. If dependent on general nervous irritability of the system, tonics, exercise, change of air, and such other constitutional measures as the peculiarities of the case may indicate, should be recommended.

The extraction of the tooth is the only remedy that can be relied upon for relief of pain arising from exostosis of the root. Dr. Good, however, thinks it may be cured in the early stages by the use of leeches and mercurial ointment.

CHAPTER TENTH.

EXTRACTION OF TEETH.

THERE are few operations in surgery that excite stronger feelings of dread, and to which most persons submit with more reluctance, than to the extraction of a tooth. Many endure the tortures of tooth-ache for weeks and even months rather than undergo the operation, and, when we take into consideration the accidents we hear of, as having occurred in its performance by awkward and unskillful individuals, it is not surprising that it should be approached with apprehension. But when performed by a skillful hand and with a suitable instrument, the operation is always safe, and in a large majority of the cases, may be effected with ease.

Dr. Fitch relates a case which will serve to illustrate the the above remarks. The subject was a man residing in Botetourt county, Virginia, who, in having the second superior molar, of the right side, extracted by a blacksmith, had a large portion of the jaw and five other teeth removed at the same time. "The fangs of his tooth," says Dr. F., "were greatly bifurcated and dove-tailed into the jaw, and would not pass perpendicularly out, though a slight lateral motion would have moved them instantly. The jaw proved too weak to support the monstrous pull upon it, and gave way between the second molar tooth and first molar, and instantly, both the anterior and posterior plates of the antrum gave way. The fracture continued to the spongy bones of the nose, and terminated at the lower edge of the socket of the left front incisor, carrying out with the jaw six sound teeth, namely, the first molar, the two bicuspid, one canine, one lateral, and one front incisor, six in all.

The soft parts were cut away with a knife. A severe hemorrhage ensued, but the patient soon recovered, though with excessive deformity of his face and mouth.”*

Dr. Cross, of Jackson, Northampton county, North Carolina, related to the author in 1838 a case so very similar to the one just quoted, that he was inclined to believe it was the same, until he recollected that the one occurred in Virginia, and the other in the county in which Dr. C. resides. The operator in this, as in the other instance, was a blacksmith, who in attempting to extract one of the superior molar teeth, brought away a piece of the jaw, containing five other teeth, together with the floor, and the posterior and anterior walls of the antrum. The piece of bone thus detached is now in the possession of a physician residing about eight miles from Jackson.

We have adverted to these cases, merely to show the impropriety and danger of entrusting the operation to individuals possessing neither knowledge of its principles, nor skill in its performance. Injuries of the jaws, occasioned by the operations of such persons, have frequently come under the immediate observation of the author, to whom it has always been a matter of surprise that an operation to which such universal repugnance is felt, should ever be confided to such persons.

The removal of a wrong tooth, or two, or even three, instead of one, are such common occurrences, that it were well if the precautions given by the illustrious Ambrose Paré were more generally observed. So fearful was he of injuring the adjacent teeth, that he always isolated the tooth to be extracted with a file before he attempted its removal. He regarded it as of the greatest importance that a person who extracted teeth should be expert in the use of his “tooth mullets; for,” says he, “unless he knows readily and cunningly how to use them, he can scarcely so carry himself, but that he will not force out three teeth at once.” Although

* Fitch's Dental Surgery, p. 347.

great improvements have been made, since his time, in the construction of instruments for the extraction of teeth, yet even now the accidents to which he alludes are almost of daily occurrence.

It is surprising that an operation so frequently called for should receive so little attention from medical practitioners, by whom, though not strictly belonging to their province, it must frequently be performed. This neglect can only be accounted for, by the too general prevalence of the supposition, that little or no surgical tact is necessary for its performance. But every physician residing in the country, or where the services of a skillful dentist cannot always be commanded, should provide himself with the proper instruments and make himself acquainted with the manner of performing the operation.

INDICATIONS FOR THE EXTRACTION OF TEETH.

With regard to the indications that determine the propriety of the operation in question, the author does not deem it necessary to say much, in this place, upon the subject, as they are so fully pointed out in other parts of the work. But, lest some of them be overlooked, he will briefly mention, in this connection, a few of the circumstances which call for the operation.

Beginning with the teeth of first dentition, it will be sufficient to state, that when a tooth of replacement is about to emerge from the gums, or has actually made its appearance, either before or behind the corresponding temporary, the latter should at once be removed; and when the aperture formed by the loss of this is so narrow as to prevent the former from acquiring its proper position, it may sometimes be necessary to extract an adjoining temporary tooth; but, for more explicit directions upon this subject, the reader is referred to what has been said on the management of second dentition. Alveolar abscess, necrosis of the walls of the alveolus, and pain in a temporary tooth, which cannot be

removed by any of the usual remedies, may, also, be regarded as indications which call for the operation.

With regard to the indications which should determine the extraction of a permanent tooth, the following may be mentioned as constituting the principal :

First, when a molar, from the loss of its antagonizing tooth, or other causes, has become partially displaced, or is a source of constant irritation to the surrounding parts, it should be removed.

Second, a constant discharge of fetid matter through a carious opening in the crown from the nerve-cavity, and the canal of the root may, also, be regarded as an indication calling for extraction. There may, however, be circumstances which would justify a practitioner in yielding to the wishes of, or even advising his patient to permit the retention of such a tooth ; as, for example, when the discharge of fetid matter is not very considerable, and the tooth is situated in the anterior part of the mouth, and cannot be securely replaced with an artificial substitute. The secretion of fetid matter, too, may, in some cases, by judicious treatment, be dried up ; in this case the tooth may, perhaps, be preserved for many years, by plugging, and the morbid influence it would otherwise exert upon the surrounding parts, be counteracted. But, it is only in the fewest number of cases, under such circumstances, that so favorable a result can be secured. A front tooth should not be sacrificed unless called for by some very urgent necessity, but neither an upper incisor nor cuspidatus should be permitted to remain in the mouth, if it exerts a manifest morbid action upon the surrounding parts. In this case the effects resulting from its retention in the mouth are worse than the loss of the tooth.

Third, a tooth which is the cause of abscess in its alveolus, should not, as a general rule, be permitted to remain in the mouth, but, as in the case last described, if it be an incisor or cuspidatus, and the discharge of matter through the gum is small, occurring only at long intervals, and, es-

pecially, if the organ cannot be securely replaced with an artificial substitute, it may be advisable to permit it to remain. But an incurable abscess in the socket of a bicuspid or molar, may be considered as constituting a sufficient indication for the removal of the tooth.

Fourth, irregularity in the arrangement of the teeth, arising from disproportion between the size of the teeth and alveolar arch, is another indication calling for the operation. But with regard to the teeth most proper to be removed, the reader is referred to the chapter on irregularity of these organs. Here he will find full directions for the management of cases of this kind.

Fifth, all dead teeth and roots of teeth, and teeth which have become so much loosened from the destruction of their sockets as to be a constant source of disease to the adjacent parts, or teeth otherwise diseased, that are a cause of neuralgia of the face, a morbid condition of the maxillary sinus, dyspepsia, or any other local or constitutional disturbance, should, as a general rule, be extracted.

There are other indications which call for the extraction of teeth, but the foregoing are among the most common, and will be found sufficient, in most cases, to determine the propriety or impropriety of the operation. Cases are, however, continually presenting themselves, to which no rules that could be laid down would be found applicable, and where enlightened judgment alone can determine the practice proper to be pursued.

In conclusion, it is scarcely necessary to say, that whenever a tooth can be restored to health, it should always be done, but tampering with such as cannot be rendered healthy and useful, and which, by remaining in the mouth, exert a deleterious influence, not only upon the adjacent parts, but also upon the general health, cannot be too strongly deprecated.

INSTRUMENTS EMPLOYED IN THE OPERATION.

Different operators employ different instruments. For about fifty years, the key of *Garengnot* was almost the only instrument used in the performance of the operation, but recently, this, in a great measure, has been superseded by forceps, which, when properly constructed, are far preferable; yet as the key is still used by some, it may be well to give a brief description of it.

KEY INSTRUMENT.

"The common tooth-key," says Dr. Arnot, "may be regarded in the light of a wheel and axle; the hand of the operator acting on two spokes of the wheel to move it, while the tooth is fixed to the axle by the claw, and is drawn out as the axle turns. The gum and alveolar process of the jaw, form the support on which the axle rolls."

Different dentists have their keys differently constructed, yet the principle upon which they all act is precisely the same. Some prefer the bent shaft, others the straight. Some give a decided preference to the round fulcrum, others to the flat, and though the success of the operator depends greatly upon the perfection of the instrument, yet he can remove a tooth more expertly by means of a key with which he is familiar, than one to which he is unaccustomed, though its construction be even better.

The author has tried almost every variety of key instrument that has been used in this country, and he is of opinion that the straight shank with a small round fulcrum, slightly flattened on each side, is decidedly preferable to any other. The objection raised to the use of such a key, by some, that it is liable to interfere with the front teeth, is without good foundation. It can be used with as much safety as a key of any construction, and, in most cases, can be as easily applied. The round is certainly preferable to

the flat fulcrum, because it is less liable to injure the gums and the alveolus. Its size should be a little larger than a half-ounce bullet.

Every key instrument should be supplied with several hooks, differing in size, to correspond to that of the teeth upon which they are to be applied. The hook described by Dr. Maynard,* is preferable to any which the author has seen. It very nearly resembles the eagle's claw, except that its curvature is rather greater. The edge of the point is about the sixteenth of an inch in width, and divided into two points, by a shallow notch, filed in the centre. A hook of this description is less liable to slip, and can be more readily applied to a tooth than those ordinarily used.

But with regard to the merits of the key instrument, compared with the forceps presently to be described, the author does not entertain a very high opinion, or of any other instrument having the same principle of action. The following remarks quoted from the late work of M. Desirabode, are in accordance with the views which he has held and promulgated for many years.

FIG. 125.

In treating of the causes of fractures of the alveoli, he says, "one of the most common, it is necessary to say it, although not a very flattering acknowledgment from our art, is a badly performed operation in the mouth, and if it

Fig. 125 represents a key instrument with a bent shank and two hooks, one for molar and one for bicuspid teeth.

* See Am. Jour. Dent. Sci. No. 3, vol. 3.

is necessary to specify cases, we would not hesitate to quote, in the first place, the use of the key of Garengéot; for we shall prove, in treating of the extraction of teeth, that this *dangerous* instrument, which is only fit to mask the unskillfulness of the operator, to the detriment of the operation, is one of the most defective of surgical instruments, and that no practitioner of good sense, being convinced of its mode of action, would attempt to employ it if he wished to extract a nail from a hole, if he did not desire to break the wall."

FORCEPS.

Forceps were not very generally or extensively employed, except for the extraction of the front teeth, until about the year 1830, but the improvements made in their construction since that period, are so great, that their use has now, among dentists, almost altogether superseded that of the key.

The forceps formerly used, were so awkwardly shaped, and badly adapted to the teeth, that the extraction of a large molar with an instrument of this description, was regarded as so exceedingly difficult, and even dangerous, that its practicability was doubted by many of the most experienced practitioners, and hence, the key was almost the only instrument resorted to for the purpose.

When we consider the strong prejudices that so recently existed to the use of forceps, it is not at all wonderful that their employment should have been resorted to with caution. Nor is it surprising that a gentleman of Mr. Bell's intelligence and practical experience, should, so late as the period of the publication of his work, 1830, tell us that the key is the only instrument to be relied on for the removal of teeth that are much decayed, and that those who have heaped the most opprobrium upon it, are glad to have a concealed recourse to its aid.

This may have been true at the time Mr. B. wrote, but it

is not now. On the contrary, cases are daily occurring of the extraction of teeth with forceps, upon which the key had been previously unsuccessfully employed. It is generally supposed that a greater amount of force is necessary to remove a tooth with forceps than with the key, but this is a mistake. It does not ordinarily require as much. All that is gained by the lever action of the key, is more than counterbalanced by the greater amount of resistance encountered in the lateral direction of the force exerted by that instrument in the removal of the tooth. But with forceps, the direction of the force being perpendicular, either upwards or downwards, as the tooth may be in the upper or lower jaw, a sufficient amount only to break up the connection with the socket, and to overcome the resistance of the walls of the alveolus, is required.

The author has used forceps exclusively since 1834, and he does not hesitate to affirm, that any tooth that can be extracted with the latter, can also be removed with the former, and that, too, in the majority of cases, with greater ease to the operator and less pain to the patient. He knows that in this expression of opinion, he differs from many of his professional brethren; and that there are many skillful and experienced practitioners, who, while they prefer forceps for the extraction of most teeth, still occasionally use the key. But he is confident, that, if they would provide themselves with forceps properly constructed for the extraction of the various classes of teeth, which they now remove with the key, and use them for six months, to the exclusion of that instrument, they would never employ it again.

It may perhaps require a little more practice to become skilled in the use of forceps than in that of the key. We would, therefore, advise those who have been accustomed to the key, not to lay it at once entirely aside; but to commence the use of forceps on teeth that are least difficult to remove, as for example, the bicuspid, and afterwards upon the molars.

But in order that forceps may be used with ease, it is ne-

cessary they should be of a proper shape and construction. Every operator should possess several pair, (seven at least,) each with a differently shaped beak, fitted to the necks of the teeth to which they are respectively designed to be applied.

For the extraction of molars, the forceps recommended by Mr. Snell are the best in use. For the upper molars two are required, one for each side, curved just below the joint, so that the jaws of the beak will form an angle with the handles, of about twenty or twenty-five degrees, just enough to clear the lower teeth. The inner blade is grooved to fit the palatine side of the neck of one of these teeth; the the outer blade has two grooves with a point in the centre to fit the depression just below the bifurcation of the two buccal roots.

Each blade of the beak of the lower molar forceps has two grooves, with a point in the centre, so situated that in grasping the tooth it comes between the two roots just at the bifurcation. Mr. Snell employs two pair for the extraction of the lower, as well as for the upper molars, in order, as he says, to have a "hook to turn round the little finger," which he supposes must be on opposite sides of the instrument. But this is rendered unnecessary by an improvement made by the author in 1833, consisting in having the handles of the instrument so bent that it may be as readily applied to one side of the mouth as the other, while the operator occupies a position at the right and a little behind the patient. By this improvement, the necessity for two pair is wholly superseded, and it moreover enables him to control the head of his patient with his left arm, and the lower jaw with his left hand, rendering the aid of an assistant wholly unnecessary.

The shape of the instrument, as improved by the author, is exhibited in the accompanying engraving, and all who use it thus improved, and it is now used by hundreds, prefer it to any other instrument they have ever employed. When applied to a tooth, the handles, as may be perceived,

turn toward the operator, forming an angle with the median line of the mouth, of about twenty-five or thirty degrees. Without this curvature in the handles, the arm of the operator would often be thrown so far from his body as to prevent him from exercising the control over it frequently required in the performance of the operation. And, while it is important that they should be bent in the manner here represented, they should, at the same time, be wide and accurately fitted to the hand.

FIG. 126.

The improvements made by Mr. Snell in the shape of the beaks of the upper and lower molar forceps, are very valuable, and for which he is entitled to much credit—more than the profession, generally, have accorded. Another, and very valuable improvement of his consists in having one of the handles bent so as to form a hook. This passes round the little finger of the operator's hand, to prevent it from slipping. In the drawings which Mr. Snell has given of his superior molar forceps, the hook is on the palatine handle of each, so that in the extraction of a right upper molar, the upper side of the instrument must be grasped, and the lower side in the extraction of a left upper molar. But the author has found that by having the handle so bent, that when applied the hook of each is next the operator, they can be more conveniently employed; and, as in the case of the lower molar forceps, the handles should be wide, and large enough to prevent them from springing under the grasp of his hand;

to which, too, they should be accurately fitted. The beak should be bent no more than is absolutely necessary to prevent the handles from coming in contact with the teeth of the lower jaw ; for in proportion to the greatness of the curvature will the force required to be applied to the instrument, be disadvantageously exerted. Every dentist, therefore, in having forceps manufactured, should give special directions with regard to their shape and size. For the extraction of the superior molars, two forceps, as has been before stated, are necessary ; one for the right and one for the left side, as represented in Fig. 127.

FIG. 127.

For the extraction of the upper incisors and cuspids, one pair only is necessary. These should be straight, with grooved or crescent-shaped jaws, accurately fitted to the necks of the teeth. They should also be thin, so that when it becomes necessary, from the decay of the tooth, they may be easily introduced under the gum, up to the edge of the alveolus. And, like the superior and inferior molar forceps,

the handles should be large enough to prevent them from springing in the hand of the operator, and a hook formed at the end of one of them.

FIG. 128.

For the extraction of the lower incisors, a pair of very narrow beaked forceps are necessary, to prevent interfering with the teeth adjoining the one to be removed. The beak below the joint of the instrument, should be bent downward so as to form an angle of about twenty-five degrees with the handles, (Fig. 129.) This, too, is one of the most useful instruments that can be employed for the extraction of roots of teeth.

FIG. 129.

Forceps for the extraction of the bicuspid should have their jaws so bent as to be easily adapted to these teeth; they should be narrow and have a deeper groove on the inside than those for the upper incisors and cuspidati, and like them should be thin, yet strong enough to sustain the pressure which it may be necessary to apply. One pair will answer for the bicuspid of both jaws, but when only one pair is employed, both handles must be straight. The engraving, Fig. 130, represents the instrument here described.

For the removal of the cuspids of the lower jaw, the hawk's-bill forceps, with crescent-shaped beaks, are often employed, but the instrument last described, and represented in Fig. 130, is better suited to the extraction of these teeth, and can be more conveniently applied and used than the other. No other instrument is required for the removal of the inferior cuspids.

FIG. 130.

The *dentes sapientiæ* in a large majority of cases, can be as readily extracted with the bicuspid forceps, as any other, and these can be as conveniently applied to the teeth of the upper as to those of the lower jaw.

But there is another kind of forceps, which can be employed for the removal of the upper *dentes sapientiæ*, when the bicuspid forceps cannot be applied. The beak of these

FIG. 131.

is bent above the joint, forming nearly two right angles, as shown in Fig. 131. These forceps, we believe, were invented by the late Dr. Edward P. Church, about the year 1830, and in those cases where the superior *dentes sapientiæ* are

considerably shorter than the second molars, they can be successfully and advantageously employed, and often times when they cannot be reached with any other extracting instrument.* These forceps are also useful in the extraction of roots of teeth, situated behind a bicuspid or molar tooth which has a very long crown.

A great variety of forceps and other instruments have been invented and used for the extraction of teeth; but the author has not seen any comparable with those which he has just described. Seven pair are all that are really necessary; and these, if properly constructed, are better and more efficient than thirty pair of the awkwardly contrived forceps which many dentists use.

The handles of a pair of forceps should be no longer than is absolutely necessary for the accommodation of the hand of the operator.

MANNER OF USING THE KEY INSTRUMENT.

The directions required for the use of the key are few and simple; but, as cases frequently present themselves to which no general rules can be applied, much will depend on the practical judgment and surgical tact of the operator. The first step to be taken in the operation, is, to separate the gum from the neck of the tooth down to the alveolus, and this should be done, not only on two sides, but all round. For this purpose, suitable knives should be provided. On the approximal sides of the tooth, a straight, narrow-bladed knife, pointed at the end, and with one cutting edge, will be found most convenient and efficient, in performing

* Dr. Church was an ingenious and talented man, and during his brief professional career—a period of about four years, he acquired a reputation for skill, which but few, in so short a time, have ever been able to achieve, and had his life been spared, he would soon have ranked among the very first practitioners in the country. Born in the western part of the state of New York, he chose the Mississippi Valley as a temporary field for his professional labors, intending ultimately to locate in Cincinnati, but during the prevalence of the Asiatic cholera, in 1832, he fell a victim to this ruthless destroyer, while on a visit to his family, in New York, in the 26th or 27th year of his age.

this part of the operation ; and it may be most effectively used, by passing the point between the neck of the tooth and gum, down to the alveolus, with the back downwards, cutting from the direction of the root towards the coronal extremity of the tooth. In this way, the connection of the gum to the sides of the neck of the tooth may be thoroughly severed. The same kind of knife or a common gum-lancet, may be used for separating the gum from the lingual or palatine, and buccal sides of the tooth. If this precaution be neglected, there will be danger of lacerating it in the removal of the tooth.

After the tooth has been thus prepared, the key, with the proper hook attached, should be firmly fixed upon it ; the fulcrum, on the inside, resting upon the edge of the alveolus, the extremity of the claw on the opposite side, pressed down upon the neck. The handle of the instrument is grasped with the right hand, and the tooth, by a firm, steady rotation of the wrist, raised from its socket. The claw should be pressed down with the fore-finger or thumb of the left hand of the operator, until, by the rotation of the instrument, it becomes securely fixed to the tooth. This precaution is necessary to prevent it from slipping—an accident that frequently happens, and one that is always more or less embarrassing to the dentist.

If the tooth is situated on the left side of the mouth, the position of the operator should be at the right side of the patient ; but, if it be on the right side, he should stand before him.

For the removal of a tooth, on the left side of the lower jaw, or the right side in the upper, the palm of the hand should be beneath the handle of the instrument ; and *vice versa*, in the extraction of one on the right side of the lower jaw, or on the left side in the upper. The manner of grasping the instrument, is, perhaps, of more importance than many imagine. If taken hold of improperly, the operator loses, to a great extent, his control over it.

The directions here given, are, in some respects, different

from those laid down by other writers ; yet, we are convinced, from much experience, that they will be found more conducive to the convenience of the operator and the success of the operation than those usually given for the use of this instrument.

There is a great diversity of opinion, as to whether a tooth should be removed inwards or outwards. Some direct the fulcrum of the instrument to be placed on the outside of the tooth, others on the inside, while others again, regard it as of little importance on which side it is placed. But experience has taught us that it should, in the majority of cases, be placed on the inside, especially of the lower teeth, as they almost always incline towards the interior of the mouth. Moreover, the edge of the alveolus is usually a little higher on the exterior edge of the jaw than on the interior ; so, that the first motion of the instrument, with its fulcrum on the outside, brings the side of the tooth against its socket, and thus, nearly double the amount of power is required to remove it ; while, at the same time, the pain and the chances of injury to the alveolar processes are very much increased.

The alveolar walls of the upper teeth are, generally, thinner than those of the lower, and do not afford so strong a support to the fulcrum of the instrument.

It is, however, frequently necessary to place the bolster of the instrument on the outside of the tooth ; especially when it is decayed in such a way, as not to afford a sufficiently firm support for the claw of the instrument. But, whenever it is possible to remove a tooth inwards, it should be done.

MANNER OF USING THE FORCEPS.

In describing the manner of using these instruments, we shall commence with the extraction of the incisors of the upper jaw. These are generally more easily removed than any of the other teeth.

After separating the gum from the neck of the tooth, the latter may be grasped with a pair of straight forceps, like those represented in Fig. 128, and pressed several times, in quick succession, outwards and inwards, giving it at the same time, a slight rotary motion, which should be continued until it begins to give way ; when, by a slight pull downwards, it is easily removed.

If the tooth is much decayed, it should be grasped as high up under the gum as possible, and no more pressure applied to the handles of the instrument than may be necessary to prevent it from slipping. Teeth are often unnecessarily broken by not attending to this precaution.

The same directions will, in most cases, be found applicable for the removal of a lower incisor. But the arrangement of these teeth are sometimes such as to render their extraction rather more difficult. The forceps best calculated for the removal of these are represented in Fig. 129.

For the extraction of a cuspidatus, greater force is usually required, than for the removal of an incisor. The straight forceps (see Fig. 128) should be employed for the removal of the superior, and curved-beaked forceps, (see Fig. 130) for the inferior cuspids. But in the extraction of one of these teeth, less rotary motion should be given to the hand than in the removal of a tooth situated in the front of the mouth. In every other respect, the operation is conducted in the same manner. The inferior cuspids usually have longer roots, and are, as a general thing, more difficult to remove than the superior.

Very little rotary motion can be given to a bicuspid, especially an upper, in its extraction. After it has been pressed outwards and inwards several times, or until it begins to give way, it should be removed by depressing or elevating the hand, as it may happen to be in the upper or lower jaw ; but for the extraction of the upper, the forceps represented in Fig. 128, and for the lower, those represented in Fig. 130, are the proper instruments to be employed, except the crown has become so much weakened by decay,

that it will not bear the requisite amount of pressure. In this case, the gum should be separated on each side from the alveolus, about an eighth or three-sixteenths of an inch above its margin, and slitted so as to admit of the application of the narrow-beaked forceps, Fig. 129. With these, the alveolar wall on each side, may be easily cut through, and a sufficiently firm hold obtained upon the root of the tooth, for its removal. These forceps will also be found better adapted for the removal of any of the back teeth or cuspids, when in a similar condition, than any other instrument.

The upper molars, having three roots, generally require a greater amount of force for their removal than any of the other teeth. They should be grasped as high up as possible, with one of the forceps represented in Fig. 127, and then pressed outwards and inwards, until the tooth is well loosened, when it may be pulled from the socket. If the forceps used for the extraction of the upper molars are of the right description, and properly applied, they will be found the safest and most efficient instruments that can be employed for their removal.

The superior dentes sapientiae are usually less firmly articulated to the jaw than are the first and second molars, and are, therefore, more easily removed than either of the last mentioned teeth. When their crowns are sufficiently long to admit of being grasped with the bicuspid forceps, (see Fig. 130,) they should be removed with this instrument, but when this cannot be applied without interfering with the anterior teeth, the forceps represented in Fig. 131, may be substituted.

The inferior molars, although they have but two roots, are often very firmly articulated, and require considerable force for their removal, and it sometimes happens, that when the approximal side of one has been destroyed by caries, the adjoining tooth has impinged upon it in such a manner as to constitute a formidable obstacle to its extrac-

tion. Two teeth are often removed in attempting to extract one when thus situated, if the precaution of filling the side of the encroaching tooth has not been previously used. This should never be omitted in the extraction of a lower molar or bicuspid, locked in the manner just described. And, though less frequently, it sometimes happens that the upper teeth impinge upon each other in the same manner, and when this occurs, the adjoining tooth should be filed sufficiently to liberate the one that is to be extracted, before attempting its removal. In applying forceps to an inferior molar, the points on the ends of the beak of the instrument should be forced down between the roots, and after having obtained a firm hold, the tooth should be forced outwards and inwards several times in quick succession, until its connection with the jaw is partially broken up, and then raised from the socket. If the tooth has decayed down to the neck, the upper edge of the alveolus may be included between the points of the beak through which they will readily pass, on applying pressure to the handles, and in this manner a secure hold will be obtained upon the tooth. The same should also be done in the extraction of a superior molar in this condition.

The *dentes sapientiae* in the lower jaw, when situated far back under the coronoid processes, are oftentimes exceedingly difficult to extract, but with forceps like those represented in Fig. 129, they may always be grasped, by a little tact on the part of the operator, except in those cases where their crowns have been destroyed by caries, when a portion of the alveoli should be cut away, either with forceps, or a strong sharp-pointed instrument, previous to attempting their removal. It occasionally happens, too, that the roots of these teeth are bent in such a manner as to constitute a considerable obstacle to their removal. But when this is the case, the roots are almost always turned posteriorly towards the coronoid processes, so that after starting the tooth, if the operator is unable to lift it perpendicularly from the socket, he will have reason to suspect its retention

to be owing to an obstacle of this nature. To overcome this, as he raises his hand, he should push the crown of the tooth backwards, making it describe the segment of a circle; for should he persist in his efforts to remove it directly upwards, the root will be broken and left in the jaw.

It sometimes happens, too, that the roots of the first and second molars of both jaws, and those of the superior dentes sapientiæ, are bent, or diverge, or converge so much as to render their extraction exceedingly difficult. The convergency of these is often so great, that in their removal, the intervening wall of the alveolus is brought away, but neither from this, nor from the removal of a portion of the exterior wall, will any unpleasant effects result. Similar malconformations are occasionally met with in the roots of the bicuspidi, the cuspidati, and even the incisor teeth.

Other obstacles sometimes present themselves in the extraction of teeth, which the judgment and tact of the operator alone will enable him to overcome. The nature and peculiarity of each case will suggest the method of procedure most proper to be pursued. The dentist should never hesitate, when necessary to enable him to obtain a firm hold upon the tooth, to embrace a portion of the alveolus between the jaws of the forceps. The removal of the upper edge of the socket is never productive of injury, as it is always, soon after the extraction of the tooth, destroyed by a peculiar operation of the economy. By this means, when the crown of a tooth has become so much weakened by disease that it will not bear the pressure of the instrument, it may be removed; and without inflicting upon the patient half the pain that would otherwise be caused by the operation.

MANNER OF EXTRACTING ROOTS OF TEETH.

The extraction of roots of teeth is sometimes attended with considerable difficulty; but, generally, they are more easily removed than whole teeth, and especially those of

the molars, for after the destruction of their crowns, an effort is usually made by the economy to expel them from the jaws, consisting in the gradual destruction and filling up of the socket, by a deposition of ossific matter at the bottom, whereby the articulation of the root becomes weakened and its removal rendered proportionately easier. The alveolar cavities are often wholly obliterated in the course of two or three years after the destruction of the crowns of the teeth, and the roots retained in the mouth, simply by their connection with the gums, so that for their removal, little more is necessary than to sever this bond of union with a lancet or sharp-pointed knife.

FIG. 132.

FIG. 133.

The instruments usually employed in the extraction of roots of teeth, are the hook, punch, elevator and screw; all of which are represented in Figs. 132 and 133. Although every dentist has them made to suit his own peculiar notions, the manner of using them, and the principle upon which they act, are the same. It will, therefore, be sufficient to say, that they should be of a convenient size,

made of good steel, and so tempered as neither to bend nor break.

The hook *a*, Fig. 132, is chiefly used for the extraction of the roots of the molar and bicuspid teeth on the left side of the mouth; the punch *b*, Fig. 132, for the removal of roots on the right side; the elevator *c*, Fig. 133, for the extraction of roots on either side, as occasion may require; and the screw *d*, Fig. 133, for the removal of the upper front teeth.

Considerable tact is necessary for the skillful use of these instruments, and this can only be obtained by practice. Great care is requisite in using the punch and elevator, to prevent them from slipping and injuring the mouth of the patient. Whenever, therefore, either of these are used, the fore-finger of the left hand of the operator should be wrapped with a cotton or linen rag, and placed on the side of the root opposite to that against which the instrument is applied, so as to catch the point in case it should slip.

But, for the removal of the roots of bicuspids and molars, and often for those of the cuspids and incisors, the narrow beaked forceps, recommended for the extraction of the lower incisors, (see Fig. 129,) may be used more efficiently than any other instrument. When the root is decayed down to the alveolus, the gum should be separated from the latter, and so much of it as may be necessary to obtain a secure hold upon the former, included between the jaws of the beak of the forceps, which, from their being very narrow, readily pass through it, and a firm hold is at once obtained upon the root; when, after moving it a few times, outwards and inwards, it may easily be removed from its socket. There are some cases, however, in which the punch, hook and elevator may be advantageously used. We have also occasionally met with cases where we have succeeded in removing roots of teeth with great ease, with an elevator shaped like the blade of a knife, by forcing it into the socket by the side of the root, and then turning it so as to make the back press against the former, and the edge against the latter.

When this instrument, which is represented in Fig. 134, is used, the blade should not be more than an inch in length, and it should be straight, short at the point, and have a very thick back, in order to prevent breaking in the operation. In using the common elevator, it is necessary that

FIG. 134.

there should be an adjoining tooth or root, to act as a fulcrum. When this can be employed, a root, or even a whole tooth, may sometimes be removed with it; but as a general rule, forceps should be preferred to any of these instruments.

For the extraction of the roots of the upper front teeth, after they have become so much funneled out by decay as to render their walls incapable of sustaining the pressure of forceps, the conical screw is invaluable. With this a sufficiently firm hold can be obtained by screwing it into the cavity for the removal of the root. But before it is introduced the softened decomposed dentine should be removed from the interior of the root, with a triangular pointed instrument like the one represented in Fig. 135.

FIG. 135.

Dr. S. P. Hüllihen invented a most valuable and useful instrument for the removal of the roots of the superior incisors and cuspids in the condition just described. It combines the advantages both of the screw and forceps, as may be seen by the accompanying cut. It is thus described by the author: "Lengthwise, within and between the blades of the beak, is a steel tube, one end of which is open; the other solid and flat, and jointed in a mortice in the male part of

the joint of the forceps. When the forceps are opened, this joint permits the tube to fall backwards and forwards from one blade of the beak to the other, without any lateral motion. Within this tube is a spiral spring, which forces up a shaft two-thirds of the tube, the other part is a well tapered or conical screw. * * * * The shaft and tube are so fitted together, and to the beak of the forceps, that one-half of the rounded part of the shaft projects beyond the end of the tube ; so that the shaft may play up and down upon the spring" about half an inch, and the screw or shaft be embraced between the blades of the beak of the instrument.

FIG. 136.

The instrument here represented, (see Fig. 136,) differs a little from Dr. Hullihen's, in the manner of its construction, though it acts upon precisely the same principle.

"The forceps," says Dr. H., "are used by first embracing the shaft between the blades."* "Then screwing it as gently and deeply into the root as possible, the blades are opened—pushed up on the root, which is then seized" and extracted.

"The screw thus combined with the forceps, prevents the root from being crushed. It acts as a powerful lever when a lateral motion is given ; it is likewise of advantage when

* The author has a pair constructed so that the upper extremity of the screw is grasped between the blades of the beak of the forceps instead of the shaft.

a rotary motion is made—it prevents the forceps from slipping, or of their action being lost, should even one side of the root give way in the act of extracting it—and is used with equal advantage where one side of the root is entirely gone.”

The opportunities which the author has had of testing the value of this instrument, have been sufficient to justify him in stating that its merits are not overrated by the inventor. Every practitioner would, therefore, do well to provide himself with one of them.

FIG. 137.

For the extraction of the roots of the upper molars, before they have become separated from each other, the forceps represented in Fig. 137, invented by Dr. Maynard, will be found highly valuable. The outer nib of each instrument is brought to a sharp point, for perforating the alveolus between the buccal roots, and for securing between them a firm hold, while the inner nib is intended to rest upon the edge of the alveolus and embrace the palatine fang. By this means a sufficiently firm hold is secured to enable the operator to remove the roots of an upper molar without difficulty; two pair, as represented in the engraving, one for the right and

one for the left side, are required. The advantage to be derived from forceps of this description, must be apparent to every dentist.

EXTRACTION OF THE TEMPORARY TEETH.

The temporary teeth should be extracted in the same manner as the permanent, and with the same instruments. If the power be properly directed, very little force is required for their removal, because the roots of these teeth have generally suffered more or less loss of substance before the operation is called for, and when they remain, the alveolar processes, at this early age, are so soft and yielding as to offer little resistance to the tooth.

The operator should be careful not to injure the pulps of the permanent teeth, or the jaw bone. Serious accidents sometimes occur from an improper or awkward removal of these teeth. But, as has been before remarked, their extraction is seldom required. It should only be resorted to for the relief of tooth-ache, the cure of alveolar abscess, to prevent irregularity in the permanent teeth, or in case of necrosis of the socket.

HEMORRHAGE AFTER EXTRACTION.

It rarely happens that excessive hemorrhage follows the extraction of a tooth. Indeed, it is oftener more desirable to promote bleeding by rinsing the mouth with warm water than to attempt its suppression. Nevertheless, cases do sometimes occur in which it becomes excessive and alarming; and it has been known, in some instances, to terminate fatally.

Excessive hemorrhage, however, does not appear to be dependent upon the manner in which the operation is performed, but rather upon a hemorrhagic diathesis of body. Hence, whenever a tendency to it exhibits itself in one member of a family, it is usually found to exist in all. Of the

many cases which have fallen under our own observation, we shall mention only one.

In the fall of 1834, Miss I——, a young lady of about fifteen years of age, called on us to have the second molar on the left side of the upper jaw removed. The hemorrhage immediately after the operation, was not greater than usually occurs, and in the course of half or three-quarters of an hour, it ceased altogether. But at about twelve o'clock on the following night, it commenced again, the blood flowing so profusely as to excite considerable alarm. A messenger was immediately sent to ask our advice, and we directed that the alveolar cavities be filled with pledgets of lint, saturated with tinct. of nut galls. Two days after, at about six o'clock in the morning, we were hastily sent for by the young lady's mother, and when we arrived at her residence, were informed that the bleeding had then been going on for about four hours. During this time more than two quarts of blood had been discharged. The blood was still oozing very fast. After we had removed the coagulum, we filled the alveolus with pieces of sponge, saturated, as the lint had been, with tinct. of nut galls. When firmly pressed in, and secured by a compress, the hemorrhage ceased. These were permitted to remain until they were expelled by the suppurative and granulative processes.

We afterwards had occasion to extract a tooth for a sister and two for the mother of the young lady, and a hemorrhage, similar to that just described, occurred in each case.

We have had, perhaps, some thirty or forty cases of this description, but never found it necessary, except in one instance, to adopt any other course of treatment than that described in the case just narrated. More powerful remedies, however, are sometimes employed. Some use a solution of the *sul. cupri*, or of the nitrate of silver, while others employ the actual cautery. But if pressure be so applied as to act directly upon the mouths of the bleeding vessels, it will almost always arrest the hemorrhage. The author has, in

two cases, found it necessary to have recourse to the actual cautery.

The following case is quoted by Dr. Fitch, from *Le Dentiste Observateur*, par H. G. Courtois, Paris, 1775.

“A person living in Paris, called on me to extract a canine tooth for him. On examining his mouth, I thought that this man was attacked with scurvy ; but this did not seem sufficient to hinder the person from having his tooth extracted, much less would he have consented to it on account of the pain which his tooth gave him. After the tooth was extracted, it did not appear to me that it bled more profusely than is customary after similar operations. In the meanwhile, the following night I was called upon to see the patient, who had continued to bleed ever since he left me. I employed, for stopping this hemorrhage, the agaric of the oak bark, which I commonly used with success. The following day I was again sent for ; the bleeding still continued. After having disburdened the mouth of all the lint pledgets, which I used for making compression at the place where the blood appeared to come from, I made the patient take some mouthfuls of water to clear his mouth of all the clots of blood with which it was filled ; I perceived, then, that the blood came no more from the place where I had extracted the tooth, but from the gums ; there was not a single place in the whole mouth from which the blood did not issue. I called in the physician, who ordered several bleedings in succession to each other, besides astringents, which were taken inwardly ; and gargles of the same nature were used ; but all these remedies, like all the others he took to give the blood more consistence, were all used to no purpose. It was not possible to stop this hemorrhage. The patient died the ninth or tenth day after the extraction of the tooth.”

Mr. Snell mentions a similar case ; it also terminated fatally.

CHAPTER ELEVENTH.

THE USE OF ANÆSTHETIC AGENTS IN THE EXTRACTION OF TEETH.

OF the various agents that have been employed for the prevention of pain during surgical operations, sulphuric ether and chloroform have proved more successful and been more generally used than any other. The practicability of doing this with the former, was first brought prominently before the medical and dental profession in 1846, by Dr. W. G. S. Morton, dentist, of Boston, Mass., and with the latter, in 1847, by Professor J. Y. Simpson, of Edinburgh, Scotland. The anæsthetic effect is obtained by inhalation of the vapor, and is supposed to be nothing more than a transient state of intoxication, which usually disappears almost immediately after the discontinuance of the administration, though in many cases it has proved fatal. For this reason, we do not think that agents capable of producing such powerful and dangerous effects as ether and chloroform, should be used in so simple an operation as the extraction of a tooth. The first, however, is less dangerous than the second. Its anæsthetic effect is also less certain and less prompt, from seven to ten minutes being usually required, whereas with the other, it is obtained in from thirty seconds to two minutes, and when ether is used, from six to ten or fifteen ounces are employed; but with chloroform, it is rarely necessary to administer more than from thirty to one hundred and fifty drops.

A number of instruments have been gotten up for the inhalation of the vapor of these agents, but the simplest and, we think, the best method of administration, is from a hollow sponge, or a napkin or pocket-handkerchief.

Although it may not always be possible, for any one, in the administration of either of the foregoing agents even to a person supposed to be free from any special proclivity to disease from organic derangement, to pronounce, *a priori*, that no bad effect will result from it; all agree that it is unsafe to give it to a patient laboring under disease of the heart, brain or lungs. The practitioner, therefore, whether medical or dental, should be well assured, before giving ether or chloroform, and especially the latter, that these organs are not only free from disease, but also from any morbid tendency, as ignorance with regard to this matter might lead to fatal consequences. It should be given cautiously under any circumstances, and the pulse should never be permitted to fall, during the inhalation, below sixty, or at most, fifty-five beats a minute; but if from carelessness or any other cause, the patient should sink and the pulsation cease, the agent should be immediately removed from the mouth, and if occupying a sitting posture, he should be placed in a reclining position, air freely admitted, cold water dashed in the face, the feet and hands rubbed with hot salt or mustard, and if necessary, artificial respiration made and galvanism applied.

It is thought by those who have had most experience in the use of ether and chloroform as anæsthetic agents, that their administration is attended with less danger when the patient is in a reclining than when in a sitting posture. This being the case, it would be well, when either is used preparatory to the extraction of teeth, to place the patient as nearly as possible in such position, and when the dentist is provided with a suitable operating chair, it can be very readily done.*

Suspension of nervous sensibility, induced by inhaling

* To admit of this, the chair of the dentist should have a movable back attached on each side, at the lower part of the seat, by a hinge, and made fast at any desired angle by means of a sort of ratchet quadrant attached to a rod passing through the back, where it comes in contact with the arm pieces, and working through a staple on the outside of each of the latter. Other chairs have also been constructed, which admit of being readily placed in almost any desired position.

the vapor of the above mentioned agents, or amylen, a more recently discovered anæsthetic, is general—every part of the body being affected alike, but partial or local anæsthesia may be procured by other and less dangerous means. Congelation or freezing, as recommended by Dr. James Arnott, of London, has been resorted to for several years, both by surgeons and dentists, and practiced to a limited extent, certainly with some success. This may be effected by applying a mixture of pounded ice and common salt in the proportion of two or three parts of the former to one of the latter, to the part on which the operation is to be performed. But in the use of this, care is necessary to prevent reducing the temperature too low, as in this case, loss of vitality would be occasioned by it. We have heard of a few cases in which this has occurred, but we believe it was owing in every instance to carelessness or want of judgment on the part of the operator, as to the length of time the application of the mixture should be continued.

Several instruments have been invented for the application of the freezing mixture to teeth preparatory to extraction. The one best adapted for the purpose, which we have seen, was designed and gotten up by Dr. Branch, of Chicago, Ill. It consists of a hollow tube about an inch or a little more in diameter, with about five-eighths of an inch on two of the sides, the one opposite the other, cut out at one end, that it may readily be placed over a tooth. To this is attached a sac, large enough to hold a table-spoonful of the mixture, of finely prepared membrane. The hollow of the tube is occupied by a steel wire spiral spring. Before using, a sufficient quantity of the freezing mixture is put in the tube; the end of the latter is placed over the tooth, when the ice and salt are forced up gently around it by pressing on the spring at the other extremity of the instrument. Two tubes are employed—one straight for teeth in the anterior part of the mouth, the other bent near one end, for the more convenient application of the mixture to a molar tooth.

The sudden application of such intense cold to a sensitive tooth, or to one which has not lost its vitality, is often productive, at first, of severe pain, and, on this account, many object to the use of it, preferring the momentary suffering consequent upon the operation of extraction, than that occasioned by the freezing mixture. But this effect is rarely experienced in the use of the agent on dead teeth, or the roots of teeth which have lost their vitality, and hence, the application of it has proved more satisfactory to such than to living teeth.

With the view of obviating the above objection to the use of cold as an anæsthetic agent, Messrs. Horne and Thornthwaite, opticians, of London, at the suggestion of Mr. Blundell, dentist, of that metropolis, contrived and constructed an apparatus, by which the temperature may be gradually diminished, say from 98° or blood heat, down to zero, or any required degree, thus preventing the pain consequent upon the sudden application of the freezing agent. The apparatus is thus described. "The required amount of water is cooled down by means of ice and salt to about zero, in a vessel called the refrigerator. To this vessel is attached another, called a graduator, containing warm water at about 100° , and so constructed as to produce a gradually diminishing temperature, for the purpose of preventing sudden shock and pain to the teeth, which a direct application of cold would inevitably cause. A tube conveys this graduating current into a terminal portion constructed of very fine membrane, which adapts itself to the form of the gums, and wholly surrounds the tooth to be withdrawn. The fluid then passes away through an exit tube. In this manner a constant current of cold, at an invariable temperature, is made to pass over the part, abstracting therefrom all heat, and with it the power of feeling." The gum and alveolar membrane being now in a frozen condition, and, as a consequence, devoid of sensibility, the extracting instrument is applied and the tooth removed.

It is difficult to understand from the foregoing descrip-

tion, the construction of the apparatus, and how the warm water first brought in contact with the tooth, is gradually displaced by the current from the refrigerator, until the temperature of the parts is reduced to the freezing point. It seems from what is said of it, to be admirably adapted to the purpose for which it was designed.

In the early part of the present year (1858) Mr. J. B. Francis, dentist, of Philadelphia, announced the discovery of a new and novel method of producing local anæsthesia, said to be peculiarly applicable to the extraction of teeth induced by passing an electro-galvanic current through the tooth the moment of its removal. The discovery was submitted to the Franklin Institute, Philadelphia, and the committee to whom it was referred for examination, composed in part of dentists, reported favorably in regard to the claims of the inventor.* One of the members of this committee, states that he had extracted between four and five hundred teeth, applying the electric current and that in ninety-five per cent of the cases without pain to his patient.†

The method of applying it is very simple. One pole, the negative is preferable, of the electro-galvanic machine is attached to one of the handles of the forceps by means of a flexible conductor, while the metallic handle of the other is grasped by the patient, the power of the current being, pre-

* The following is an extract from the report referred to above. "The Committee is satisfied, from the observation and experiment of its members, that in a large majority of cases of extraction with this apparatus, *no pain whatever* is felt by the patient.

To test the question whether the effect might not be simply mental, the circuit was broken without the patient being aware of it, when the usual pain was experienced, although, in the same patient, and on the same occasion, teeth had been removed while the current was flowing without causing pain.

In the less successful cases, the teeth were broken and diseased below the level of the gum, and the pain, in adjusting the forceps previous to the completion of the circuit and the extraction, considerable.

The sensation produced by the passage of the current is not painful, it being so adjusted as to be *just perceptible* to the patient. The committee believes its use to be entirely without danger, and not likely to be followed by any unpleasant after effects."

† W. S. Wilkinson.

vious to the operation, graduated by the piston of the coil, while the patient holds the forceps in the other hand. The current should only be sufficiently powerful to be distinctly felt. The circuit through the tooth is not made until the instant the operation begins. This part is managed by an electro-magnet closing and breaking the circuit through the conductors of the positive and negative poles and the body of the patient. This may be done either by the foot of the operator, or by an assistant.

A small electro-galvanic battery, arranged for the purpose having been placed in the office of the author, soon after the announcement of the discovery, he has had frequent opportunities of applying this new agent in the extraction of teeth, and thus far, about nine out of ten of those who were placed under its influence, while undergoing the operation, assured him that they either experienced no pain at all, or only very little—not a tenth part of what they had experienced under the operation on former occasions. In almost every case in which the tooth was grasped, without the instrument coming in contact with anything more than the edge of the gum the operation appeared to be painless, or very nearly so. But when pushed up a considerable distance between it and the tooth, the suffering was not appreciably diminished, the electric current in such cases seeming to be too much diffused. It is stated by those who have made the experiment that this diffusion of the electric current may be prevented by insulating the outer portion of the instrument with a coating of gutta-percha or by japaning. The author has not tried this expedient.

How it is that the passage of an electric current through a tooth should prevent pain is, to the author, inexplicable, but that it does in a majority of cases, is attested by many who have been placed under its influence. It may be nothing more than a mere change of sensation, and whether its application will become general, or its efficacy as an anæsthetic agent be fully established, remains for future experience to settle.

As the use of anæsthetic agents of any kind in the extraction of teeth is attended with inconvenience, nearly always procrastinating the operation, the author is of opinion that their employment, as a general thing, should be dispensed with. He never encourages their use, and rarely finds it necessary to employ them. Indeed the extraction of a tooth is so simple an operation, seldom requiring more than from two to five seconds for its performance, that most persons would rather submit to it at once, than have it procrastinated by the application of an agent for the prevention of the momentary pain which it occasions.

CHAPTER TWELFTH.

ATROPHY OF THE TEETH.

THAT peculiar structural alteration of the teeth, designated atrophy, is less frequent in its occurrence than any other disease to which these organs are liable, and as the progress of the affection usually terminates with the action of the causes concerned in its production, it has scarcely been deemed of sufficient importance to merit serious consideration. Hence neither its ætiology nor pathology has been very carefully investigated. Indeed, most writers upon the diseases of the teeth have overlooked the affection altogether, while a few have only merely alluded to it, without describing the characteristics even of its principal varieties. Whether we shall now be able to throw any additional light upon the subject, or establish the correctness of any opinions already advanced, or not, we leave to others to determine.

The strict applicability of the term atrophy, as the two principal varieties of the affection consist rather in a congenital defect, most frequently of some portion of the enamel of two or more teeth, than wasting from want of nourishment, of any of the dental tissues, may, perhaps, be considered as somewhat questionable. This would seem to be rendered still more so by the fact, that neither of the varieties to which we have referred, occurs subsequently to the formation of the enamel. But as the congenital form of the disease is evidently the result of altered function in a portion of one or more of the formative organs, if not of absolute degeneration, from vicious nutrition, we are disposed to regard the term as the most applicable of any that can be applied to it.

Mr. Fox speaks of a defect, sometimes met with in the

organization of the enamel, characterized by yellow color, and a great number of indentations upon its surface, giving to the teeth the appearance of "the exterior of a sponge," which he termed "honey-combed." He refers these defects to a deviation from the natural action of the membrane which secretes the enamel, and dependent upon some "peculiarity of constitution," during the first months of infancy. He thinks it is liable to occur in several children of the same family, and that teeth thus affected are less liable to decay than those which have beautiful and transparent enamel.*

M. Delabarre, an ingenious physiologist, and for the most part, a close and very accurate observer, has, probably, approached nearer a correct explanation of the true cause of odontatrophia than any other writer. But he has evidently confounded one of the varieties of the affection with erosion—a disease characterized by essentially different phenomena, and produced by different causes. He restricts the term to the variety which consists simply of discoloration and absence of a portion of the enamel. In the former cases he believes it may be congenital or accidental, but in the latter he thinks it is always congenital. He confounds the variety which consists of perforations in the enamel with erosion.† But, so distinctly marked are the peculiarities of each, there is no necessity for confounding the one with the other.

The opinion of M. Delabarre, with regard to the cause, is founded upon the supposition, that the doctrine of the formation of the enamel as maintained by Hunter, Jourdain, Fox and Cuvier, is erroneous, and that this portion of a tooth is formed from an immense number of exhalents which cover the crown, forming a "sort of imperceptible velvet."‡ These he regards as integral parts of the tooth, and believing the enamel fibres to be secreted by them, he ascribes the

* Natural History and Diseases of the Human Teeth ; American edition, pages 57, 8 and 9.

† *Traité de la Seconde Dentition*, pp. 20, 1, 2 and 3.

‡ It is scarcely necessary to state that the exhalents of Delabarre, correspond exactly with the corpuscles or fibres of the enamel membrane of Raschkow.

affection under consideration to their vicious development or imperfect nutrition.

Lefoulon adopts the views and almost the precise language of Delabarre, in the description which he gives of the affection. Maury treats of both it and erosion as being one and the same disease. But in describing atrophy he notices the distinctive peculiarities by which each affection is characterized.* In describing the difference between erosion and atrophy, M. Delabarre says, the part atrophied is deformed and deprived of the enamel, "that the teeth are yellow and sensitive, the touch of the finger causing pain." In erosion, if the crystals of the enamel are not wholly destroyed, "the bottom of the pits are of a white color, and on being touched no disagreeable sensation is experienced; if, on the contrary, the crystals are destroyed to the dentine, the part thus denuded is irritable."

In an article on erosion, Maury gives a very accurate description of several varieties of atrophy of the teeth. The first, he represents as consisting of irregular white, deep or light yellow spots, situated in the enamel of the tooth, without affecting the smoothness of its surface. The second, as characterized by little crowded holes, or irregular depressions, resembling quilting; or as consisting of transverse sinuosities, single or divided by prominent lines, which are sometimes "yellow, but of the color of the enamel." The third variety affects the dentine as well as the enamel, reducing the dimensions of the crown of the tooth sometimes to one-third of its natural size, and not unfrequently dividing it by a deep circular groove or depression.

Not one of the phenomena here described is produced by the action of corrosive agents, or is the result of chemical decomposition either of the enamel or dentine, but are manifestly dependent upon other causes. The term erosion, therefore, cannot be applied to either variety of the affection just noticed, with the least show of propriety.

* *Traité Complet de l'Art du Dentiste*, pp. 99 and 100.

Odontatrophia may very properly be divided into three varieties.* Each has distinctive peculiarities which characterizes it from either of the others. Two are always congenital, and the other, although most frequently congenital, sometimes occurs subsequently to the eruption of the tooth.

Although Maury has given a better description of the three principal varieties of dental atrophy than any other writer, he has omitted some things which it will be proper to mention. But in treating of these different varieties, we shall change, somewhat, the order of the arrangement which he has laid down.

First variety. The peculiarities that distinguish this variety of atrophy from either of the others are, that it never impairs the uniformity and smoothness of the surface of the enamel, and is characterized by one or more white, or dark or light brown, irregularly shaped spots, upon the labial or buccal surface of the tooth. It occurs oftener than the third variety, and less frequently than the second. It rarely appears on more than one or two teeth in the same mouth, though several are sometimes marked by it. It is seen on the molars more frequently than the bicuspid, and much oftener on the incisors of the upper jaw than any of the other teeth. We do not recollect to have ever observed it on the cuspids of either jaw, nor on the palatine or lingual surfaces of the incisors.

The enamel is much softer on the affected than on the unaffected parts of the tooth, and may be easily broken and reduced to powder with a steel instrument. It seems to be almost wholly deprived, in these places, of its animal constituents as well as its connection with the subjacent dentine.

The size of the atrophied spots are almost as variable as their shape, but the only harm resulting from them, is the unpleasant aspect they sometimes give to the tooth.

As we have before remarked, this variety of atrophy is sometimes accidental, occurring subsequently to the eruption of the tooth, but in a large majority of the cases it is

congenital. It is rarely seen on a temporary tooth. In all the cases which have come under our observation it was confined, to the best of our recollection, to the teeth of second dentition.

Second variety. This may be very properly denominated *perforating* or *pitting* atrophy, as it gives to the enamel an indented or pitted appearance, the irregular depressions or holes extend transversely across and around the tooth. The pits are sometimes more or less distinctly separated one from another, by prominent lines; at other times they are confluent, and form an irregular horizontal groove. Sometimes they penetrate but a short distance into the enamel; at other times they extend entirely through it to the dentine. Their surface though generally rough and irregular, usually presents a glossy and polished appearance—a peculiarity which always distinguishes this variety of the affection from erosion. The pits often have a dark brownish appearance, though sometimes they are of the color of the enamel on other parts of the tooth.

This variety of atrophy is never confined to a single tooth. Two, four, six or more corresponding teeth are always affected at the same time, in each jaw, and the corresponding teeth of the same class precisely in the same manner, and in the same place. When more than two are marked, the distance of the pits from the coronal extremities of the organs varies, according to the progress the formation of the enamel had made on each class at the time of the operation of the causes concerned in the production of the affection. For example, when the line of pits in the central incisors is situated about two lines from their cutting edges, it will scarcely be one line from the cutting edges of the laterals, and only the points of the cuspids will be marked. When the indentations are nearer the edges of the central incisors, they will be on the edges of the laterals, and the cuspids will have entirely escaped.

Sometimes the teeth are marked with two or three rows of pits, and when this is the case, the patient has either had

two or three relapses or been attacked two or three times in quick succession with different diseases capable of interrupting the progress of the formation of the enamel.

Although the incisors are more frequently marked with these indentations than any of the other teeth, the cuspids, bicusps, and even the molars are sometimes affected with them. When the disease attacks the molars, its effects are generally located on the grinding surface. The permanent teeth are more liable to be attacked than the temporary. We have never known but one instance in which the latter were affected with the disease.

This variety of atrophy occurs oftener than either of the others, and though it sometimes gives to the teeth a very disagreeable and unsightly appearance, it rarely increases their liability to decay.

Third variety. In this variety of atrophy the whole or only a part of the crown of a tooth may be affected—the dentine being often implicated as well as the enamel. The tooth usually has a pale yellowish color, a shrivelled appearance, and is partially or wholly divested of the enamel. Sometimes the crown is not more than one-half or one-third its natural size. Its sensibility is usually greatly increased, and its susceptibility to pain from external impressions is wonderfully excited by acids. It is also more liable than the other teeth to be attacked by caries. The root of the tooth, though rarely, is nevertheless sometimes affected, and presents an irregular knotted appearance.

The disease is often confined to a single tooth, but it more frequently shows itself on two corresponding teeth in the same jaw. According to our observation, the bicusps are more liable to be attacked than any of the other teeth. The temporary teeth are rarely affected with it.

This variety of atrophy occurs less frequently than either of the others, and although it increases the liability of the affected organs to decay, they sometimes escape its attacks to the twentieth or thirtieth year of age.

In the description which we have given of the three va-

rieties of dental atrophy, we may have omitted to mention some of the peculiarities belonging to each, but we believe we have pointed out their principal characteristics with sufficient accuracy to enable almost any one to distinguish one from another, and either from erosion.

CAUSES.

The first variety is evidently produced by some cause capable either of preventing or destroying the bond of union between the enamel and subjacent dentine, but what that cause always is, is a question which it may be difficult to answer. Subsequently to the eruption of the teeth, it may be occasioned by mechanical violence, but we have never known but one case in which it had resulted from this cause, and that was occasioned by a blow upon the tooth.

Now, whether the bond of union between this portion of the enamel and the subjacent dentine was immediately destroyed by the concussion of the blow, or whether it resulted from subsequent inflammation and the death of the intermediary membrane, is a question which it may not be easy to answer. If it were destroyed at once by the blow, one would be led to suppose that the change in the color of the enamel would have been observed immediately, but this may have resulted from some subsequent change or alteration in the animal constituents of this part of the enamel, which followed as a consequence of the injury produced by the violence of the blow. These are questions, however, which the present state of our knowledge does not enable us to solve. But that the white spot in this case resulted as a consequence of the blow, there cannot be the least shadow of doubt.

But when the affection is congenital, as it almost always is, it is dependent upon some other cause, possibly upon disease in the pulp, or intermediary membrane, which constitutes the bond of union between the dentine and enamel, subsequently to the formation of the latter. But what the

determining cause of the disease of these parts is, if the affection be produced in this way, whether simple local irritation, or general constitutional disturbance, we are not prepared to say. One would be likely to suppose, if the atrophied spots were occasioned by disease of the pulp or intermediary membrane, the morbid action would scarcely confine itself to such narrow and circumscribed limits. But, whether the destruction of the intermediary membrane of the affected part results as a consequence of actual disease, or merely from vicious nutrition, or whether from some unknown cause, it has failed to be developed here, it is certain that the fibres of this portion of the enamel are not united to the subjacent dentine; and, not receiving a supply of nutrient fluid or vital principle, their animal frame work partially or wholly perishes, leaving but little more than their inorganic constituents.

The cause of this variety of congenital atrophy, it must be confessed, is very obscure; and in the absence of positive knowledge, we can only infer the cause from the nature of the affection. If it does not result from one or other of the above mentioned, it is difficult to imagine in what way it is produced.

The cause of the second variety of odontatrophia is, we think, susceptible of a more satisfactory explanation. The formative organ of the enamel, as is now generally admitted, consists of a membrane, composed almost wholly of short hexangular corpuscles or fibres, which correspond in shape and arrangement to the fibres of the enamel. This membrane is accurately moulded to the crown of the tooth, and according to Raschkow, each fibre is a secretory duct, whose peculiar function it is to secrete the fibre of the enamel corresponding to it. It should also be borne in mind that the secretion of the earthy salts of the enamel commences at the coronal extremity of the tooth, gradually proceeding towards the base of the crown. Now we can readily conceive that some constitutional disease, by interrupting the secretion of the earthy salts deposited in the enamel cells or secretory

ducts of the enamel membrane, for the formation of the enamel fibres, by occurring at the time when this process is going on, might prevent them from being filled, and cause them to wither or waste away, giving to this portion of the enamel the pitted appearance which characterizes this variety of atrophy. In other words, the secretion of the inorganic constituents of the enamel being interrupted for a short time, the horizontal row of cells in the enamel membrane, into which it should be deposited, will not be filled, consequently, as might readily be supposed, they will waste away, leaving a circular row of indentations around the crown of the tooth. But as soon as the constitutional disease has run its course, the secretion of the earthy salts will be resumed, and unless the child experiences a relapse, or has a second attack of disease, capable of interrupting this secretory process, the other parts of the enamel will be well formed.

Some writers ascribe the formation of these pits in the enamel to the chemical action of a corrosive fluid, or to an acidulated condition of the fluid contained in the dental sacs, but those who have done so, have confounded the affection with erosion. We believe, however, it nearly always occurs as a consequence of an eruptive disease or catarrhal fever during the "enameling" process, and there are many facts which go to sustain the correctness of this opinion. In nearly all the cases that have fallen under our observation, it was clearly traceable to measles, scarlatina, chicken pox, catarrhal fever, or small pox. It may, however, occasionally be produced by other constitutional diseases.

The third variety of dental atrophy, so far as our observations upon the subject would seem to justify an opinion, always results from altered or vicious nutrition, caused by disease of the pulp or enamel membrane, or both, during the secretion of the dentine or enamel, according as one or both are affected. We are inclined to believe that the disease in the dental pulp or enamel membrane may be produced either by local or constitutional causes, or both. But

the information which we have been able to obtain concerning the state of the general health, and that of the mouth at the time of the dentinification of the pulp and the secretion of the enamel, in the cases that we have seen, has not been as satisfactory as we could have wished.

Since writing the foregoing, the following interesting case of dental atrophy has fallen under our observation :

Mrs. C. called, December 16, 1850, to consult us concerning her daughter's teeth, which, from congenital defect, presented a most unsightly appearance. The girl was between nine and ten years of age. The cutting edges of the upper central incisors were badly pitted and very rough; the corresponding teeth in the lower jaw had a transverse row of pits passing around them, about a sixteenth of an inch below their cutting extremities. Another row of pits, so close together as to form a rough groove, encircled the upper central incisors, about an eighth of an inch below the gum, and the laterals a little nearer their cutting edges; the lower incisors were similarly marked, but not quite so near the gum. The enamel, near the second transverse row of pits, and between it and the incisive extremities of the teeth, was thin and of a light brown color. A little above the first row, on the central incisors, were two or three brown or opaque spots. The first permanent molars were also encircled with a row of indentations, about half way between their grinding surfaces and the gums.

On inquiry, we learned from the mother that the child had a light attack of measles when between eleven and twelve months old; of scarlet fever when about fifteen or sixteen months of age, and dysentery at about the twenty-first or twenty-second month.

Now, here we have the three varieties of atrophy on the same teeth, and the occurrence of constitutional diseases about the time when the affected parts of the teeth must have been receiving their earthy salts, would seem to establish, very conclusively, the connection of the one with the other.

T R E A T M E N T .

The nature of this affection is such as not to admit of cure. The treatment, therefore, must be preventive rather than curative. All that can be done is to mitigate the severity of such diseases as are supposed to produce it by the administration of proper remedies. By this means, the effects may, perhaps, be partially or wholly counteracted.

It seldom happens that atrophied teeth decay more readily than others, so that the only evil resulting from the affection, is a disfiguration of the organs. When the cutting edges of the incisors only are affected, the diseased part may sometimes be removed with a file without inflicting the slightest injury on the teeth.

CHAPTER THIRTEENTH.

NECROSIS OF THE TEETH.

By the term necrosis, when applied to a tooth, is meant the death of the entire organ, or of the crown and inner walls of the root, for it often happens that a degree of vitality is kept up in the outer portion of the dentine and the investing cementum by the peridental membrane, long after the destruction of the pulp and lining membrane. When other bones are affected with necrosis, the dead part is thrown off, and the loss supplied by the formation of new bone. But the teeth are not endowed either with exfoliative or recuperative powers.

The density of a tooth is not sensibly, if at all, affected by the mere loss of vitality, but so great a change takes place in the appearance of the organ, that it might readily be detected by the most careless observer. After the destruction of the lining membrane, the tooth gradually loses its peculiar semitranslucent and animated appearance, assuming a dingy or muddy brown color, and this change is more striking in teeth of a soft than in those of a hard texture. The discoloration, too, is always more marked when the loss of vitality has resulted from a blow, than when produced in a more gradual manner. The discoloration is partly owing to the presence of the disorganized matter in the pulp-cavity, and partly to the absorption of this matter by the surrounding walls of dentine.

After the destruction of the lining membrane, the tooth may receive a sufficient amount of vitality from the alveolar dental periosteum to prevent it from exerting a manifest morbid influence upon the parts with which it is immedi-

ately connected. Teeth have occasionally been retained under such circumstances with apparent impunity for fifteen or twenty years. But when every part of a tooth has lost its vitality, it becomes an extraneous body, and when this happens, inflammation of the socket ensues; the gum around it becomes turgid and spongy, bleeds from the slightest injury, and the organ gradually loosens and ultimately drops out. In the mean time, the diseased action frequently extends to the sockets and gums of the adjoining teeth.

The front teeth, from being more exposed to injuries from blows, are more liable to necrosis than the molars.

C A U S E S .

Necrosis of the teeth may be produced by a variety of causes, such as protracted fevers, the long continued use of mercurial medicines, and by caries. The immediate cause, however, when not occasioned by a blow sufficiently violent to destroy the vascular connection of the tooth with the rest of the system, is inflammation and suppuration of the lining membrane, or it may result from deficiency of vital energy and impaired nutrition. The author has met with several cases in which the loss of vitality could not be accounted for in any other way.*

T R E A T M E N T .

When a tooth, deprived of vitality, is productive of injury to the gums and to the adjacent teeth, it should be immediately removed; for, however important or valuable it may be, the health and durability of the others should not be jeopardized by its retention.

When necrosis of a tooth is apprehended, we should endeavor, by the application of leeches to the gums, and gargling the mouth with suitable astringent washes, to prevent its occurrence. If this plan of treatment is adopted at

* Vide Spontaneous Disorganization of the Dental Pulp.

an early period, it will sometimes prevent the loss of vitality; but if long neglected, a favorable result need not be anticipated.

When the loss of vitality is confined to the crown and inner walls of the root, if the former is not seriously impaired by caries, it may be perforated, and the pulp-cavity and root cleansed and filled in the manner as directed in another part of this work. If the necrosed tooth is an incisor, the perforation should be made from the palatine surface, provided the approximal surfaces are sound. But previously to the introduction of a filling, the decomposed surfaces of the walls of the pulp cavity should be completely removed, and if this does not restore to the tooth its natural color, the cavity should be filled with raw cotton, saturated with a solution of chloride of soda, as directed in another chapter.

8

CHAPTER FOURTEENTH.

EXOSTOSIS OF THE ROOTS OF THE TEETH.

THIS disease is common to all bones, but it rarely attacks any other part of a tooth than the root, and usually commences at or near the extremity, then extends upwards, covering a greater or less portion of the external surface. It sometimes, however, commences upon the side of the root and forms a large tubercle; at other times the deposit of the new bony matter is spread over its surface, often uniformly, but more frequently unequally. The osseous matter thus deposited, is usually of the color, consistence and structure of the cementum, though sometimes it is a little harder and assumes a yellower tinge. Indeed, the enlargement is supposed to be a mere hypertrophied condition of this substance.

FIG. 138.

The deposit of osseous matter, is sometimes so considerable, that the roots of two or more teeth are firmly united by it. The author has several examples of exodontosis of this description. One of the above was presented to him by Drs. Blandin and Reynolds, of Columbia, South Carolina. These with many other examples are in the Mu-

seum of the Baltimore College of Dental Surgery. There is one there of three teeth thus united.*

* This was presented to the author for the above Institute, by Dr. Hawes of New York.

The most extraordinary example of dental exostosis which the author has ever seen was sent to him for examination by Dr. V. M. Swazey, dentist, of Easton, Pa. The tooth apparently is a dens sapientiae, and the formation of the exostosis must have commenced with the dentinification of the pulp. It had spread over every part of the tooth, the crown as well as the root; it had ruptured and penetrated every part of the enamel membrane, but had not wholly destroyed the function of this organ, as nodules of enamel are seen in various parts of the exostosis. The tumor, including the tooth, is about as large as a common sized hickory nut.

Exodontosis often continues for a long time without producing any inconvenience whatever. It usually first manifests itself by slight soreness in the affected tooth, which increases as the fang becomes enlarged, until pain, either constant or periodical, and of a character more or less severe, is experienced.

The most remarkable case of exodontosis on record, is related by Mr. Fox. The subject was a young lady, who, at the time she came to Mr. F., had suffered so much and so long, that the palpebrae of one eye had been closed for near two months, and the secretion of saliva had, for some time, been so copious, that it flowed from her mouth, whenever opened. She had tried every remedy science and skill could suggest, without experiencing any permanent benefit, and was only relieved from her suffering by the extraction of every one of her teeth.

In the course of the author's practice, he has removed many teeth affected with exostosis, but has never met with a case similar to that described by Mr. F. In one instance, he was compelled to extract four sound teeth and nine roots; yet the pain was not, at any time, severe, but it was constant, and a source of great annoyance to the patient. The following is one among the many cases which have fallen under his observation:

Mr. S., of Baltimore, having suffered some time from pain

in his first left superior bicuspid, applied to a dentist in 1843, for the purpose of having the tooth removed. In the operation, the root, about three-sixteenths of an inch from its extremity, was fractured and left in the socket. In consequence of this, the gnawing pain with which he had for a long time before been troubled, continued, and at the expiration of twelve months, the gum over the remaining portion of the root became very much swollen, puffing out the lip to the size of half a hen's egg. The tumor, after a few days, was opened, and a large quantity of dark colored, purulent, fetid matter, was discharged, which, for a short time, gave considerable relief. The tumor, however, was re-formed and opened some four or five times in about that number of months. In the fall of 1845, he called upon us for the purpose of obtaining advice. At this time his gum was swollen, and the upper lip puffed out in the manner as just described. On opening the tumor, about three table-spoonfuls of black matter, resembling thin tar, escaped. We then found, upon examination, that the outer wall of the antrum, immediately over the remaining portion of the root of the first bicuspid, was destroyed, and there was an opening through it large enough to admit the fore-finger. Believing that the extremity of the root left in the socket was the cause of the disease, we immediately proceeded to extract it, which we succeeded in doing by the removal of the outer wall of the alveolus. The root was found, on removal, to be enlarged by exostosis, to the size of a very large pea. The operation proved perfectly successful, the secretion of purulent matter soon ceased, and in a few weeks he was completely relieved from the troublesome affection under which he had so long labored.

CAUSES.

The primary cause of this disease does not appear to be well understood. Most writers concur in attributing the proximate cause to irritation of the periosteum of the fang,

but this is not, as some suppose, necessarily dependent upon any morbid condition of the crowns themselves, for it often attacks teeth that are perfectly sound. It seems rather to be attributable to some peculiar constitutional diathesis.

TREATMENT.

The disease having established itself does not admit of cure, and when it has progressed so far as to be productive of pain and inconvenience to the patient, the loss of the affected teeth becomes inevitable. When the enlargement is very considerable and confined to the extremity of the root, and has not induced a corresponding enlargement of the alveolus around the neck of the tooth, the removal of the affected organ is often attended with difficulty, and can only be effected by removing a portion of the socket, or fracturing it.

CHAPTER FIFTEENTH.

SPINA VENTOSA OF THE TEETH.

Among the diseases which attack the teeth, Mr. Fox mentions spina ventosa, but the author is of the opinion that the name is not strictly applicable to the affection which he treats of under that designation. In medical language, this term is used to designate a disease consisting of an ulcerated bony tumor caused by internal caries, and attended by a prickling sensation of the flesh.

Mr. Fox describes the disease as being seated in the cavity of the tooth, and "the vessels ramifying on its membrane," he says, "acquire a diseased action by which the membrane becomes thickened, absorption of some of the internal parts of the tooth takes place, and the opening, at the extremity of the fang, also becomes enlarged. This disease of the membrane is attended with the formation of matter, discharging itself at the point of the fang, into the alveolar cavity, which, being rendered more porous by the process of absorption, affords an easy exit. During the progress of the disease, the gum, covering the alveolar process, becomes inflamed, and acquires a spongy texture: the matter, passing from the socket, makes its escape into the mouth by several openings through the gum, which is thus kept in a constant state of disease."

Now, it will be perceived, that there is little or no analogy between spina ventosa and the disease spoken of by Mr. F. under that name. The latter is nothing more than the effects of alveolar abscess, arising from inflammation and suppuration of the lining membrane.

When matter is confined in the cavity of the tooth, the canal in the root may become greatly enlarged. The author has met with many cases where this has happened, and he has in his possession several examples of teeth thus affected.

If, previously to the suppuration of the lining membrane and pulp, the tooth is affected with exostosis, the disease would then resemble spina ventosa.

CAUSES.

The enlargement of the opening at the extremity of the root, is not, as Mr. Fox believes, caused by the action of the absorbents. Before this takes place, the lining membrane has been destroyed, and the vital powers of the root so much reduced as to preclude the possibility, even admitting that the absorbents are capable of effecting such enlargement, of its being accomplished through their agency.

The enlargement is wholly attributable to the action of the corrosive matter contained in the root. This explanation appears the more probable when we consider that the matter discharged from the socket, is ichorous, offensive, and of a corrosive character.

Moreover, spina vetosa is characterized by exterior enlargement of the bone, while, in the disease in question, the size of the root is seldom increased. The external appearance of the organ is that of a necrosed tooth.

TREATMENT.

A tooth affected with this disease does not admit of cure. The proper treatment, therefore, consists in the prompt removal of the organ. There are no local nor general remedies which can be applied, capable of affording relief. The symptoms, perhaps, may sometimes be palliated, but it is not advisable to tamper with a tooth thus affected, as it will only serve to protract and ultimately to augment the evil.

It is possible that the occurrence of the affection might, in some cases, be prevented by prompt antiphlogistic treatment; such as recommended for the prevention of necrosis, and for the cure of tooth-ache caused by inflammation of the lining membrane. But after suppuration has taken place, and a secretion of fetid and corrosive matter been kept up until the canal of the root has become enlarged, the proper remedial indication is the removal of the tooth.

CHAPTER SIXTEENTH.

DENUDING OF THE TEETH.

THIS is one of the most remarkable affections to which the teeth are liable. It consists in the gradual wasting of the enamel on the labial surfaces, attacking first the central incisors, then the laterals, afterwards the cuspids and bicuspid, extending, sometimes, to the first and second molars. It usually forms a continuous horizontal groove, as regularly and smoothly constructed as if it had been made with a file. See Fig. 139. After it has removed the enamel, it commits

FIG. 139.

FIG. 140.

its ravages upon the subjacent dentine, sometimes penetrating to the pulp-cavity. It rarely changes the color of the enamel, but the dentine, after it becomes exposed, assumes first a light, and afterwards a dark-brown color, retaining, however, a smooth and polished surface. But this destructive process does not always commence at a single point on the labial surface of the central incisors, in the manner as just described; it sometimes attacks several points simultaneously. (See Fig. 140.) As it spreads, these unite, and ultimately a deep excavation is formed, with walls so smooth and highly polished that the tooth presents the appearance of having been scooped out with a broad, square, or round-pointed instrument.

The progress of the affection is exceedingly variable. It is sometimes so rapid that the dentine becomes exposed

within two or three years from the time of its attack; at other times its effects upon the enamel is scarcely perceptible for six or eight years after the discovery of its occurrence. The author was acquainted with a lady whose teeth were thus affected and the denuding process did not perforate the enamel for nearly twenty years.

C A U S E S .

The cause of this singular affection has never been satisfactorily explained. It was first noticed by Mr. Hunter, who calls it decay by denudation, and supposes, "from its attacking certain teeth rather than others, and from its being confined to a particular tooth," that it is a disease inherent in the tooth itself, and not dependent on circumstances in after life.

Mr. Bell thinks Mr. H. has confounded the affection with another, similar in its appearance, but arising from a wholly different cause.

He says, quoting Mr. Hunter's remarks, "I have seen instances where it appeared as if the outer surface of the bony part, which is in contact with the inner surface of the enamel, had first been lost, so that the attraction of cohesion between the two had been destroyed; and as if the enamel had been separated for want of support, for it is terminated all at once." "In this passage, Mr. Hunter describes very accurately the result of superficial absorption of the bony structure, a circumstance which I have occasionally seen, though more rarely than the present abrasion of the enamel, with which it cannot for a moment be considered as identical. In one case the enamel is gradually and slowly removed by a regular and uniform excavation; in the other, the abruptness and irregularity of the edges, show that it had broken away at once, from having lost its subjacent support. The cause of the former is external; in the latter it is within the enamel."

Mr. Bell, in attempting to correct one error, has fallen into another, equally great and palpable. He attributes the breaking in of the enamel to absorption of the subjacent dentine, instead of ascribing it to decomposition by chemical agents, which is the true cause.

In almost every instance, where the author has found the edges of the enamel in the condition as described by Messrs. Hunter and Bell, he has also observed that the surface of the exposed dentine was decayed.

But the breaking in of the enamel is not the affection now under consideration. That is the result of caries of the subjacent dentine; this a sort of spontaneous abrasion.

Mr. Bell is unfortunate, also, in the suggestions which he throws out in regard to the cause of the disease. "Whatever may be the cause," says he, "and at present I confess myself at a loss to explain it, the horizontal direction in which it proceeds, may, I think, be connected with the manner in which the enamel is deposited during its formation; for it will be recollected, that it first covers the apex of the tooth, and gradually invests the crowns by *successive circular depositions*; it is, therefore, not improbable, that from some temporary cause, acting during its deposition, certain circular portions may be more liable to mechanical abrasion, or other injury than the rest."

This conjecture, though it may seem somewhat plausible, is far from satisfactory. If, as he supposes, certain circular portions of the enamel are less perfectly formed than others, and consequently rendered more liable to the disease, it would not be wholly confined to the anterior surface of the tooth, but would extend entirely around it, and as soon as these imperfectly formed circular portions were destroyed, its ravages would cease.

Mr. Fox frankly acknowledges his inability to assign any cause for this affection; but conjectures that it is dependent on some solvent quality of the saliva. Were this supposition correct, every part of the tooth would be alike subject to its attacks.

Other writers suppose it is occasioned by the friction of the lips. But this hypothesis is destitute of the least semblance of plausibility. The narrowness and depth of the grooves are sometimes such as to preclude the possibility of the contact of the lips with the interior surfaces. Some authors, again, believe it to be attributable to the use of tooth brushes ; but this is an equally gratuitous supposition.

The dentine, after it is denuded of enamel, is generally quite sensitive, and very susceptible of heat and cold.

The author is of the opinion that the loss of substance which characterizes the affection, is produced by the action of acidulated buccal mucus. In every other part of the mouth this fluid is mixed with saliva, and the acid it contains so much diluted as to prevent it from acting on other portions of the teeth. That this is the true cause, is rendered almost certain by a case, which, a few years since, fell under the observation of Dr. Eleazar Parnly, where the crowns of human teeth which were used for dental substitutes, were attacked in the same manner, thus proving, conclusively, that the loss of substance was caused by the action of chemical agents.

T R E A T M E N T .

As a preventive, Mr. Fox recommends the avoidance of whatever tends to produce it, but unfortunately he leaves his readers entirely in the dark upon this subject. In advanced stages of the affection, the author has often succeeded in arresting its progress, by widening the groove at the bottom, and afterwards filling it with gold. This, in the majority of cases, will prove successful.

CHAPTER SEVENTEENTH.

SPONTANEOUS ABRASION OF THE CUTTING EDGES OF THE FRONT TEETH.

FIG. 141.

THE spontaneous abrasion of the cutting edges of the front teeth, is an affection of very rare occurrence. It commences on the central incisors, and from thence

proceeds to the laterals, the cuspids, and sometimes, though very rarely, to the first bicuspid. Teeth thus affected, have, when the jaws are closed, a truncated appearance; the upper and lower teeth do not come together, and are rather more than ordinarily susceptible to the action of acids, and of heat and cold. In other respects, little or no inconvenience is experienced from it until the crowns of the affected teeth are nearly destroyed.

Its progress, as in the case of abrasion of the labial surfaces, is exceedingly variable. It sometimes destroys half or two-thirds of the crowns of the central incisors in two or three years; at other times, seven or eight years are required for the same effect to be produced by it. In one case which came under our own observation, the abrasion had extended to the bicuspid; and the central incisors of both jaws were so much wasted, that on closing the mouth, they did not come together by nearly three-eighths of an inch; and but two years had elapsed since its commencement. In another case, where it had been going on for seven years, it

FIG. 141 represents a case of spontaneous abrasion, taken from a drawing given by Mr. Bell.

had not extended to the cuspids, and the space between the upper and lower incisors, did not exceed an eighth of an inch. The subjects of both were gentlemen—the first aged about twenty-eight, and the other twenty-one.

Mr. Bell gives an interesting case of a gentleman whose teeth were thus affected:—"About fourteen months since, 1831, this gentleman," says he, "perceived that the edges of the incisors, both above and below, had become slightly worn down, and, as it were, truncated, so that they could no longer be placed in contact with each other. This continued to increase and extend to the lateral incisors, and, afterwards, successively, to the cuspidati and bicuspidis. There has been no pain, and only a trifling degree of uneasiness, on taking acids, or any very hot or cold fluids, into the mouth. When I first saw these teeth, they had exactly the appearance of having been most accurately filed down at the edges, and then perfectly and beautifully polished: and it has now extended so far, that when the mouth is closed, the anterior edges of the incisors of the upper and lower jaws are nearly a quarter of an inch asunder. The cavities of those of the upper jaw must have been exposed, but for a very curious and beautiful provision, by which they have become gradually filled by a deposit of new bony matter, perfectly solid and hard, but so transparent that nothing but examination by actual contact, could convince an observer that they were perfectly closed. This appearance is exceedingly remarkable, and exactly resembles the transparent layers which are seen in agatose pebbles, surrounded by a more opaque mass. The surface is uniform, even, and highly polished, and continuous, without the least break, from one tooth to another. It extends at present, to the bicuspidis, is perfectly equal on both sides, and when the molars are closed, the opening, by this loss of substance in front, is observed to be widest in the centre, diminishing gradually and equally on both sides to the last bicuspidis."

Dr. J. D. McCabe described to the author, in 1837, a case

he had seen a short time before, very similar to the one mentioned by Mr. B. He also gave him the name and age of the individual and the length of time the abrasion had continued ; but these he does not recollect with sufficient accuracy to repeat.

CAUSES.

With regard to the cause of this most extraordinary affection, Mr. Bell, referring to the case which he describes, says, he is "wholly at a loss to offer even a conjecture." "It cannot have been produced by the friction of mastication, for these teeth have never been in contact since the first commencement of the affection ; nor does it arise from any apparent mechanical cause ; for nothing is employed to clean the teeth, excepting a soft brush. Absorption will equally fail to account for it ; for not only would this cause operate, as it always does, irregularly, but we find that, instead of these teeth being the subjects of absorption, a new deposition of bony matter is, in fact, going on, to fill the cavities which would otherwise be exposed."

Mr. Bell is correct in supposing that it is not the result either of mechanical action or absorption. If then, neither of these agencies are concerned in its production, it must be the result of some chemical action, though not of the salivary fluids of the mouth, for if it was, every part of the exterior surfaces of the teeth would be acted on alike. This, as well as the affection last noticed, the author is disposed to believe, is produced by the action of acidulated mucus. The anterior surfaces of the upper front teeth not being so frequently washed by the saliva, the mucous secretions of the upper lip, are often permitted to remain on these portions of the teeth for a considerable length of time, and to the presence of this, when in an acidulated condition, we believe the denuding process to be attributable, while the abrasion of the cutting edges of the incisors and cuspidati is caused by acid mucus, secreted by the mucous follicles of

the end of the tongue, which is brought in contact with the cutting extremities of the front teeth almost constantly, and we believe it is in this way that their loss of substance is effected.

Dr. Nuhn, a German physician, describes a gland which he has recently discovered in the interior of the tip of the tongue. It is represented as having a number of ducts opening through the mucous membrane over it. It is thought to be a mucous gland, and it may be, that this gland in peculiar idiosyncrasies, secretes the acidulated mucus concerned in the production of the affection under consideration. But, whether this hypothesis be correct or not, it is evidently the result of the action of a chemical agent, and that this is furnished by the end of the tongue is rendered more than probable from the fact, that it is brought in contact with the cutting edges of the teeth, almost every time the mouth is opened.

TREATMENT.

This, like some of the other affections of the teeth, cannot be cured. If the tendency to an acidulated condition of the mucous secretions of the mouth could be overcome or counteracted, its progress, perhaps, might be arrested. But, this is a branch of practice that comes rather within the province of the medical than the dental practitioner, so that any directions upon the subject here are unnecessary.

CHAPTER EIGHTEENTH.

MECHANICAL ABRASION OF THE TEETH.

WERE it true, as declared by Richerand, that the loss of the enamel occasioned by friction, is repaired by a new growth, it would never suffer permanent loss from mechanical abrasion ; but, the assertion is not only untrue, but too absurd to need refutation.

The teeth rarely suffer loss of substance from friction when the incisors of the upper jaw shut in front of those of the lower. It is only when the former fall plumb upon the latter, that mechanical abrasion of the cutting edges can take place, and when this happens, they sometimes suffer great loss of substance. The crowns of these teeth are occasionally worn entirely off, while those of the molars and bicuspid are, comparatively, little affected. The reason of this is, that when the upper and lower front teeth strike plumb upon each other, the lateral motions of the jaw not being restricted, the friction is greater at the anterior, than at the posterior part of the mouth ; consequently, the front teeth will suffer more from abrasion than the molars.

Sometimes, the whole of the teeth are worn off alike ; at other times, owing to the peculiar manner in which the jaws come together, it is confined to only a few.

Mr. Bell believes that certain kinds of diet tend, more than others, to produce abrasion of teeth. To establish his belief, he tells us that sailors, who, the greater portion of their lives, live on hard biscuits, have only a small part of the crowns of their teeth remaining above the edges of the gums. But the loss of substance is not produced so much by the friction of masticating certain sorts of diet as by the

action of the lower teeth upon the upper, when those of the superior and inferior maxillary sustain the relationship to each other, just described.

When the front teeth of the lower jaw strike against the palatine surface of those of the upper, the latter are sometimes worn more than three-fourths away, and in some instances, entirely up to the gums. We have seen the teeth of some individuals so much abraded, in this way, that but little of their crowns remained, except the enamel of their anterior surfaces.

The wearing away of the crowns of the teeth would expose the lining membrane, were it not that nature, in anticipation of the event, sets up an action by which the pulps are transformed into a substance called *osteo-dentine*, which is identical in structure with cementum. By this beautiful operation of the economy, the painful consequences that would otherwise result, are wholly prevented.

The loss of the crowns of the upper incisors and cuspids may sometimes be advantageously replaced with substitutes attached to the remaining roots of the natural organs. See Manner of Preparing a Natural Root and Inserting a Pivot Tooth.

CHAPTER NINETEENTH.

FRACTURES AND OTHER INJURIES OF THE TEETH FROM MECHANICAL VIOLENCE.

THE injuries to which teeth are subject from mechanical violence, are so variable in their character and results, as to render a detailed description impossible. The same amount of violence inflicted upon a tooth does not always produce the same effect. The nature and extent of the injury will depend as much upon the physical condition of the teeth, the state of the constitutional health and the susceptibility of the body to morbid impressions, as upon the violence of the blow. Thus, a blow sufficiently severe to loosen a tooth, might not, in one case, be productive of any permanent bad consequences, while in another, it might cause the death of the organ and inflammation of the adjacent parts, as well as necrosis of the alveolus.

A tooth of compact texture, and in a healthy mouth, may be deprived of a portion of its substance without any serious injury; but a similar loss of substance of a tooth, not so dense in its structure, would be likely to produce inflammation and suppuration of the lining membrane, and possibly of the alveolo-dental periosteum. Hence, in order to form a correct opinion of the result of injuries of this sort, we must take into consideration, not only the character of the tooth upon which the blow has been inflicted, but also the state of the health of the mouth and of the individual.

If the tooth is not loosened in its socket, any injury resulting from the loss of a small portion of the enamel, or even of the dentine, may be prevented by smoothing the

fractured surface with a file, that the juices of the mouth and particles of extraneous matter, may not be retained in contact with it. But if the tooth is loosened, and inflammation of the investing membrane supervene, leeches should be applied to the gums, and the mouth washed several times a day, with some astringent lotion, until the inflammation subsides.

When a tooth has been displaced from its socket by a blow, and its vascular connection with the general system destroyed, necrosis must, as a necessary consequence, be the result. An imperfect union between the tooth and alveolus may sometimes be established by the effusion of coagulable lymph, and the formation of an imperfectly organized membrane; but the tooth will ever after, from the slightest cold, or derangement of the digestive organs, be liable to become sore to the touch, and in most cases will ultimately assume a muddy-brown, unhealthy appearance.

The author has, on several occasions, replaced teeth that had been knocked from their sockets; but in only two instances was the operation attended with anything like success. The subject in one case was a healthy boy, of about thirteen years of age, who, while playing bandy, received a blow from the club of one of his playmates, which knocked the left central incisor of the upper jaw entirely out of its socket. He saw the boy about fifteen minutes after the accident. The alveolus was filled with coagulated blood. This he sponged out, and, after having bathed the tooth in tepid water, carefully and accurately replaced it in its socket, and secured it there by silk ligatures attached to the adjacent teeth. On the following day, the gums around the tooth were considerably inflamed; to reduce which, he directed the application of three leeches, and the frequent use of diluted tinct. myrrh, as a wash for the mouth. At the expiration of four weeks, the tooth became firmly fixed in its socket, but from the effusion of coagulable lymph, the alveolar membrane was thickened, and the tooth, in consequence,

somewhat protruded. A slight soreness, on taking cold, has ever since been experienced.

Dr. Noyes, dentist, of Baltimore, mentioned to the author, a case of a somewhat similar character. The subject was a boy of about ten years of age. One of his front teeth was forced from its socket by a fall. It was replaced shortly after, and in a few weeks, became firm in its alveolus. Mr. Bell also mentions a case, attended with a like result.

The alveolar processes and jaw-bones are sometimes seriously injured by mechanical violence. In 1834, the author was requested by the late Dr. Baker, of Baltimore, to visit, with him, a lady who, by the upsetting of a stage between Washington and Baltimore, had her face severely bruised and lacerated. All that portion of the lower jaw, which contained the six anterior teeth, was splintered off, and only retained in the mouth by the gums and integuments, with which it was connected. The wounds of her face, having been properly dressed, the detached portion of the jaw was carefully adjusted and secured by a ligature passed around the front teeth and first molars, and by a bandage on the outside, around the chin and back part of the head. Her mouth was washed, five or six times a day, with diluted tinct. of myrrh. The third day after the accident, by the direction of Dr. B., she lost twelve ounces of blood; and, in five or six weeks, with no other treatment than the dressing of the wounds, she perfectly recovered.

It often happens, that the crown of a tooth is broken off at the neck. We have known the crowns of four, and in one case of thirteen teeth to be fractured from a single blow. The subject of the last case was a fireman of Baltimore, who, in 1835, received an accidental blow in his mouth from the head of an axe, which broke off the crowns of all the upper and lower incisors, two cuspids and three of the bicuspids of the inferior maxillary. The subject of the other case was a boy about twelve years of age, who, from a similar accident, occasioned by running up suddenly behind a man who was chopping wood, had the crowns of his upper

incisors broken off. In both of these cases, the inflammation which supervened was so great as to render the removal of the roots necessary. The crowns, fangs, and alveolar processes, are sometimes ground to pieces, or the teeth driven into the very substance of the jaw. Mr. Bell says, he once found a central incisor so completely forced into the bone, that he thought it to be the remains of a fang, but, on removing it, found it to be an entire tooth.

When the crown of a tooth has been broken off by a blow, the root should, as a general rule, be immediately extracted because the injury it has received will seldom permit it to remain with impunity. We have sometimes engrafted artificial crowns on such roots, but the practice is usually a bad one. If the tooth is to be replaced with an artificial substitute, the root should be first extracted.

But, whether the loss of the crown be replaced or not, the root can seldom remain without injury, for after the inflammation, induced by the concussion of the blow, has sufficiently subsided, or terminated in suppuration of the lining membrane, which it usually does, it acts as a morbid irritant to the socket and adjacent parts, and for this reason should be removed.

CHAPTER TWENTIETH.

DISEASES OF THE DENTAL PULP AND PERIOSTEUM.

THE pulp of a tooth, from the high degree of vitality with which it is endowed, is one of the most sensitive structures of the body, and like other parts is liable to become the seat of various morbid phenomena. Its susceptibility, too, to morbid impressions, is influenced by a variety of circumstances, such as temperament, habit of body, the state of the constitutional health, the condition of the hard structures of the tooth, etc. A cause, which under some circumstances would not be productive of the slightest disturbance, might, under others, give rise to active inflammation, together with all its painful and disagreeable concomitants. Increased irritability may exist independently of any organic change, either in the pulp, dentine or enamel. Examples of this are often met with in females during gestation; but it arises more frequently as a consequence of caries of the tooth than from any other cause. Even before the disease has penetrated to the central chamber of the organ, the pulp, either from functional disturbance arising from decomposition of the dentine, impaired relationship between the two, or from being more exposed to the action of external deleterious agents, often assumes a most wonderful and marked increase of irritability. Impaired digestion, as well as a disordered state of other functions of the body, frequently produces the same effect.

The susceptibility of the pulp to impressions of heat and cold, and of acids, is always increased by heightened irritability. When this exists to any considerable degree, the

mere contact of these agents with the tooth, is often productive of severe pain, which, on their removal, usually, very soon subsides. The pulp, however, may remain in this condition for months, and even years, without becoming the seat of inflammatory action.

Preternatural sensibility of the dentine,* whether in a sound or partially decomposed state, augments very appreciably, the irritability of the pulp. Impressions of heat and cold conveyed through the conducting medium of a metallic filling, or of a thin covering of dentine, as sometimes happens when a considerable portion of the tooth has been worn away, is also a very frequent cause of heightened irritability of the pulp. With its susceptibility thus increased, the impressions produced by these agents are often a source of irritation, and even of inflammation and suppuration, causing the death of the entire crown and inner walls of the root of the tooth. At other times, the irritation is only followed by slight increase of vascular action and an effusion of plastic lymph over the affected part of the pulp, which is gradually converted, first into *callus*, and then into *osteo-dentine*; thus an additional barrier is interposed between it and the irritating agents.

I R R I T A T I O N .

The pulp of a tooth may become the seat of severe pain when there is no inflammation in it. The slightest increase of vascular action, when this organ is in a preternaturally irritable condition, is productive of more or less irritation. The pressure of the slightly distended vessels upon the nervous filaments distributed upon it, at such times, is sufficient to cause great pain.

Impressions of heat and cold are conveyed more readily to the pulp when the dentine is in a morbidly sensitive condi-

* The sensibility of dentine is sometimes so much increased that the mere contact of a hard substance with a part which has become exposed by the destruction of a portion of the enamel, is often productive of severe pain.

tion, and when this is the case, they produce a more powerful effect.

The remedial indications of pain in a tooth arising simply from irritation of the pulp, consists in the removal of the primary and exciting causes. When produced by impressions of heat and cold conveyed to it through the conducting medium of a metallic filling, and intervening supersensitive dentine, the filling, if the severity and continuance of the pain is such as to warrant the belief that it will give rise to inflammation, should be removed and some non-conducting substance placed in the bottom of the cavity previously to replacing it. If this is done before inflammation actually takes place, it will prevent subsequent irritation from these causes. It is worthy of remark, however, that the pain thus produced, is in proportion to the sensibility of the subjacent dentine. If this is destroyed previously to filling the tooth, their action upon the pulp will be as effectually prevented as by the interposition of a non-conducting substance. But in the application of agents for this purpose, there is danger of destroying the vitality of the pulp. The employment of them, however, is resorted to more frequently to prevent pain during the removal of caries than subsequent irritation from impressions of heat and cold.

Arsenious acid, cobalt, chloride of zinc, and the actual cautery, have all been employed in the treatment of sensitive dentine.

The use of arsenious acid in dental practice, has hitherto been chiefly confined to the destruction of the vitality of the pulps of teeth, but it will also destroy the sensibility of the dentine, and thus enable the operator to remove the semi-decomposed parts of a sensitive carious tooth, preparatory to filling, without pain. In employing it for this purpose, however, great care is necessary to prevent the destruction of the vitality of the pulp, and the injection of the vessels of the dentine with red blood. This is very liable to happen when applied to a tooth of a very soft texture, especially

if in the mouth of a young person, and when the caries extends nearly to the pulp-cavity. The action of the arsenic, through the intervening hard structures, on the pulp, would seem, in the first instance, to cause, in some way or other, the decomposition of the red globules of the blood, whereby a pinkish-purple tinge is imparted to the serous portion of this fluid, which is conveyed to every part of the dentine. It seems, too, to exert some peculiar action upon the microscopic vessels of this tissue, for the fluid which they circulate is now evidently everywhere effused from their coats and brought in direct contact with the earthy salts, coloring them so deeply as to impart to the crown of the tooth a pinkish or purple hue, distinctly seen through the translucent enamel covering. Three or four cases in which this has happened have occurred in the practice of the author.

But the application of arsenic to a tooth is not necessarily followed by this effect. It is only in young persons, and in teeth of a very soft texture, that it is liable to be produced, unless it is permitted to remain in the tooth a long time. When it is used merely for the purpose of destroying the vitality of the surface of the dentine at the bottom of the cavity, preparatory to the introduction of a filling, and to prevent irritation of the pulp from impressions of heat and cold, it should never be permitted to remain more than two hours. At the expiration of this time it should be removed and after thoroughly washing and drying the cavity, the filling may be introduced, without danger of subsequent irritation of the pulp or discoloration of the tooth. The thirtieth, fortieth, or even fiftieth part of a grain, with an equal quantity of sulphate of morphia, is sufficient to apply to a tooth. It should be placed directly upon the bottom of the cavity, on a dossil of raw cotton or lint, moistened with creosote. After the arsenic has been applied, the cavity should be carefully filled with wax, mastic, or Hill's stopping, to prevent the possibility of its escaping into the mouth and to exclude the buccal fluids. When the cavity

is in the approximal surface of the tooth, additional security may be obtained by passing a ligature of floss silk three or four times around it and tying. A small ring cut from the end of a tube of caoutchouc placed on the tooth is even better than a ligature of silk.

Professor Arthur recommends the use of cobalt for destroying morbid sensibility of dentine. He has used it for several years, and believes it to be as certain in its effects as arsenious acid and less liable to injure the pulp of the tooth. It is the arsenic, however, with which the cobalt is combined that produces the effect, but Professor A. is of the opinion its union with this renders it less liable to be taken into the dentine by absorption, and as a consequence, less liable to produce a deleterious action upon the pulp. It is used in the form of a brownish-black oxyd, reduced to a fine powder, and applied to the tooth in the same manner as arsenious acid.

But for the destruction merely of morbid sensibility of the solid structures of a tooth, chloride of zinc, according to the author's experience, although somewhat less certain in its effects, is superior to any preparation dependent for its active properties upon the presence of arsenic. With this agent it rarely happens that more than five minutes are required to obtain the desired effect. Although a powerful escharotic, it does not, as all arsenical preparations are liable to do, produce any deleterious effect on the pulp of the tooth. When first applied, it excites a sensation of heat, followed by burning pain, but these soon subside, and on removing it from the tooth, the parts of the cavity with which it was in contact, will, in a large majority of the cases, be found totally insensible to the touch of an instrument. Dr. F. N. Seaburg, in the *Dental Times*, relates a case in which he applied it directly to the exposed pulp of an aching tooth. The pain, which at first was increased, soon subsided, and after removing the chloride, the tooth was filled in the usual way, without inconvenience to the patient.

The chloride may be applied directly to the cavity of a sensitive tooth, without being combined with any other substance, on a little raw cotton or lint, or it may be made into a paste by mixing it with an equal quantity of flour, the moisture which it absorbs from the atmosphere being sufficient for the formation of the paste, or it may be mixed with a little pure anhydrous sulphate of lime, in an impalpable powder, and then applied to the tooth. But before this is done, as much of the decomposed dentine as possible should be removed, and the application should be held firmly in contact with the part of the cavity upon which it is desired that it should act. This may be done by filling the cavity after it has been put in, with softened wax or raw cotton. The chloride may remain in the tooth from five to ten minutes, or until the burning sensation produced by it ceases. A single application will generally suffice to destroy the sensibility of the walls of the cavity to a sufficient depth to enable the operator to remove any remaining portions of decayed dentine without pain, and to obtund the vitality of the floor of the bottom sufficiently to prevent the transmission of impressions of heat and cold to the pulp. A second, and even a third application, however, will sometimes be required.

The actual cautery was at one time much used and highly recommended by French dentists in the treatment of sensitive decayed teeth, but the use of it was long since laid aside by American and English dentists, as the application gave rise, very often, to inflammation of the pulp.

Less potent agents, such as pulverized galls, tannic acid, &c., have been employed for the purpose of destroying morbid sensibility in teeth preparatory to filling, and sometimes with good results.

Having noticed the agents usually employed for destroying morbid sensibility in dentine as a means of preventing irritation, from impressions of heat and cold, of the dental pulp, we will proceed to notice a few of the non-conductors of caloric that have been used for the accomplishment of the

same object. Among the substances which have been employed for this purpose, are, *asbestos*, *gutta percha*, *Hill's stopping*, which is a compound of gutta percha, carbonate of lime and some other earthy salts, *cork* and *oiled silk*.

Asbestos, as a non-conductor of caloric, certainly possesses every desirable property, and is as indestructible in a tooth as gold. When used for this purpose, the purest variety should be selected. A small pellet, made from the filaments of this mineral, placed in the bottom of a cavity in a tooth previously to filling, will effectually prevent irritation of the pulp from impressions of heat and cold. The cavity, however, should be first properly prepared, washed with tepid water and made perfectly dry. The asbestos may occupy from one-fourth to one-sixth of the depth of the cavity after the filling has been introduced and consolidated.

A thin layer of gutta percha placed in the bottom of the cavity, previously to introducing the gold, is as effectual in preventing the transmission of impressions of heat and cold, as asbestos, and can be more conveniently applied. There is, however, a preparation of it, known as "*Hill's stopping*," better than the simple article. The method of applying it is very simple. The cavity being first properly prepared, a small piece of this preparation is slightly warmed by a fire, or by the flame of a candle or lamp, then placed in the bottom of the cavity and adapted to its inequalities by pressing on it gently with a large broad-pointed plugger. This done, the cavity may be filled with gold in the usual manner.

Cork, though an equally good non-conductor of caloric, is thought by some, as it is more destructible than asbestos or gutta percha, to be objectionable, but cut off, as it necessarily would be in the bottom of the cavity beneath the filling, its liability to undergo any change, would seem to be rendered wholly impossible. The only valid objection to its use, is, that it is of a more porous nature than gutta percha, and cannot be adapted as perfectly to the inequalities of the floor of the cavity. In consequence of this, there is danger in intro-

ducing the filling of forcing some portions of the gold through it, unless a very thick piece be used. Oiled silk has also been used in some cases very successfully, but it is not as good a non-conductor as any of the before-mentioned agents.

But a metallic filling is not the only medium through which impressions of heat and cold are conveyed to the dental pulp. When the dentine on the coronal extremity or side of a tooth becomes very thin from loss of substance, occasioned either by mechanical or spontaneous abrasion, the use of the file, erosion, or other cause, the pulp sometimes becomes painfully affected by the action of these agents. Loss of substance from any of these causes, is also often attended by exalted sensibility of the exposed dentine; and when this is the case, the contact of acids with it is productive of more or less pain. Nature, however, usually employs means to prevent the painful consequences that would naturally arise from continued abrasion of the coronal ends of the teeth and the consequent exposure of their nervous pulp, consisting in the gradual ossification of this organ, so that by the time it would become exposed, it is converted into osteo-dentine. But this does not always take place in time to prevent irritation and pain.

When irritation of the pulp occurs in a tooth that has been filed on one or both sides, so much so as to leave only a thin covering of dentine, the best known means of preventing morbid sensibility is, to keep the filed surface constantly clean by frequent friction, both with a brush and waxed floss silk, or some other suitable substance. This operation should be repeated after each meal, and in the morning immediately after rising, and at night before going to bed.

When caries has extended to the central cavity, irritation is often produced by contact of partially decomposed portions of dentine or other foreign matter with the pulp. The proper remedial indication in such cases, it is scarcely necessary to say, consists in the removal of whatever matter from the tooth that can act either as mechanical or chemical irri-

tants. This done, the cavity in the tooth—supposing the pulp to be in a healthy condition—should be properly filled.

But when the irritation arises as a consequence of exalted irritability and increased vascular action of the pulp, dependent upon disease or altered function of some other part or parts of the body, the remedial indications are different. The treatment then should be addressed to the primary affection. Examples of this sort are of frequent occurrence. They are met with almost daily, particularly in females during gestation, and in dyspeptic individuals, and persons affected with gout and chronic rheumatism. They are also sometimes met with in individuals who have been exposed to miasmatic emanations of marshy districts, when the irritation assumes an intermittent form, occurring at stated intervals of twenty-four, forty-eight or seventy-two hours, and continuing from one to three hours. Some of the worst forms of tooth-ache are produced by one or other of these causes.

The local disturbance, when it occurs in females during pregnancy, may generally be removed by mild aperients, warm foot-bath and anodynes at night on going to bed. When it depends upon other kinds of derangement of the uterine organs, treatment suited to the peculiar indications of the case should be instituted. When it occurs in a person affected with dyspepsia, rheumatism or gout, the constitutional treatment required by the particular disease, constitutes the proper remedial indication. When the irritation assumes an intermittent form, an emetic or cathartic, followed by quinine, will generally put a stop to the local disturbance, provided it has no connection with caries of the crown of the tooth.

INFLAMMATION.

The pulp of a tooth, when healthy, has a grayish-white appearance, and its capillaries are invisible to the naked eye,

but when it becomes the seat of *acute* or *active* inflammation, they may be distinctly seen—the organ having assumed a bright red color. Inflammation having established itself, soon extends to every part of the pulp, and even to the alveolo-dental periosteum. When permitted to run its course uninterruptedly, it usually terminates in suppuration in from three to eight or ten days.

The unyielding nature of the walls of the cavity in which it is, on all sides, enclosed, renders expansion of the pulp impossible, and as its capillaries become distended with blood, they press on the nervous filaments which are everywhere distributed upon it, causing at first constant *gnawing*, but afterwards, as the distention of the vessels increases, severe, and sometimes almost insupportable, *deep-seated throbbing* pain.

Inflammation may attack the pulps of sound teeth as well as those affected with caries, but it occurs more frequently in the latter than in the former, and it is oftener met with before than after the pulp has become actually exposed. The severity of the pain, however, is determined by the condition of the tooth, the state of the general health, and the causes concerned in its production. The pulp, when in an irritable condition, is more liable to become the seat of acute inflammation than when in a perfectly healthy state, and the occurrence of suppuration is soon followed by alveolar abscess, unless an opening is made immediately through the crown, neck or root of the tooth for the escape of the matter.

The effusion of lymph which takes place during the inflammatory stage, and which, under other circumstances, and when the inflammation is less severe, is made to play an important part in the reparation of the injury, compresses the pulp into still narrower limits as it accumulates in quantity, and, thus, becomes an additional source of irritation, adding fuel to the flame already lighted up.

Inflammation of the pulp may be caused by a blow on the tooth; by impressions of heat and cold conveyed to it

through the conducting medium either of the enamel and dentine, or a metallic filling, or by the pressure of a filling, or the direct contact of external irritating agents, as disorganized portions of the tooth, particles of alimentary substances, acrid humors, etc. But, as we have stated in another place, *inflammation* of the dental pulp "is not always a necessary consequence of impressions" of heat and cold; pain may be produced by them when it does not exist, but in this case it usually subsides soon after the removal of the irritant. The pulp of a tooth may be exposed for months, and subjected several times a day to the actual contact of foreign bodies, without becoming the seat of acute inflammation. The irritation and increased vascular action thus occasioned, are, no doubt, removed by the effusion of lymph to which they give rise, and the pulp, after it has become exposed, having room to expand as its vessels become distended, does not suffer irritation from the pressure to which it would otherwise be subjected.

When suppuration takes place, the pain very nearly ceases, but the tooth for a time remains sore to the touch, and its appearance is changed. It has no longer the peculiar animated translucency of a living tooth, but has assumed an opaque, muddy or brownish aspect. With the disorganization of the pulp, the entire crown and inner walls of the root lose their vitality; still, if the alveolo-dental periosteum has not become seriously involved in disease, the vascular and nervous supply furnished the exterior of the root, is often sufficient to prevent the tooth from exerting a manifestly obnoxious influence upon the surrounding and more highly vitalized parts. The cementum being more analogous in structure to true osseous tissue than dentine, now plays an important part in the animal economy. It being more liberally supplied with the nutritive juices and vitality, and not being sensibly affected by the death of the other parts of the organ, it keeps up the living relationship of the tooth with the alveolo-dental periosteum, at least sufficiently to prevent it from acting perceptibly as a morbid irritant.

Inflammation of the pulp of a tooth, besides the local pain with which it is attended, often gives rise to a train of constitutional morbid phenomena, usually of a mild, but sometimes of an aggravated and even threatening, character. Among these are *head-ache, constipation of the bowels, furred tongue, dryness of the skin, quick, full and hard pulse, ear-ache, ophthalmia, disease of the maxillary sinus*, etc.

The amount of constitutional disturbance arising from inflammation of the pulp of a tooth, depends on the state of the general health, and the nervous irritability of the system at the time. In the majority of cases it occasions but little inconvenience, and disappears as soon as the inflammation ceases, but sometimes it assumes a very alarming character. A case of fatal tetanus, produced by inflammation of the pulp of a lower molar, occurred a few years ago in Baltimore. The subject was a young lady about eighteen years of age. The system, at the time, from great bodily fatigue and mental excitement, was in an exceedingly irritable condition, but in other respects, though constitutionally rather delicate, she was in the enjoyment of good health.

There is not an organ or tissue of the body in which acute inflammation is more intractable in its nature, and rapid in its progress, than in the pulp of a tooth; and, when we take into consideration its situation, and physical and vital peculiarities, it is not to be wondered that it should, in so large a majority of the cases, terminate in the disorganization of the part. Still it may sometimes be arrested, and the remedial indications here, though they cannot be as readily and fully carried out, are the same as for inflammation in any other part of the body. The first and most important one consists in the removal of all local and exciting causes. If it be the result of irritation produced by the pressure of a filling, the plug should be immediately removed, leeches applied to the gum of the affected tooth, and, if the patient be of a full habit, blood may be taken from the arm, and a brisk saline purgative prescribed. The removal of the filling, however, when the

inflammation has previously made much progress, will not prevent suppuration, but it may prevent it from extending to every part of the pulp. When an external opening is made for the escape of the matter the moment suppuration takes place, the remaining portion of the pulp will be relieved from pressure, the cause of the irritation, and then the inflammatory action may cease. But if the matter remains in the central cavity of the tooth, the part of the pulp which has not suppured will still be subjected to pressure, and the inflammation and suppuration will go on until the entire organ perishes. Nor will the disorganizing process stop here. The alveolo-dental membrane, at the extremity of the root, will soon become implicated, and in a short time alveolar abscess will form, thus terminating the acute stage of the disease.

There may be no indications of irritation or inflammation for several weeks, or even months, after a tooth has been filled, but at the expiration of this time, the pulp, from increased irritability, caused, perhaps, by some change in the state of the patient's general health, may be attacked by inflammation. Although this very seldom happens, it does, nevertheless, sometimes occur, and, when there is reason to apprehend that it is about to take place, and it may be suspected if pain is felt in the tooth when anything hot or cold is taken into the mouth, or if it becomes the seat of gnawing or gradually increasing pain, the filling should be moved. If the pain now ceases, a thick layer of gutta percha, or "Hill's stopping," may be placed in the bottom of the cavity, and the filling replaced, using the precaution, as before directed, to introduce the gold in such a way as to prevent the liability of depressing the floor of the cavity. But if the pain and inflammation continues unabated, it may be necessary to extract the tooth, or expose the pulp and destroy its vitality by applying to it some powerful escharotic, as arsenious acid, which, acting more promptly and with more certainty than any other, seems best adapted to the purpose. When this is done, it is usually with the

view of securing the retention and preservation of the tooth by filling the pulp-cavity and root, an operation now very frequently performed by many dentists.

The abstraction of blood directly from the pulp, one would suppose, would be better calculated to arrest the inflammation than almost any other treatment, but we do not think this has been resorted to for this purpose sufficiently often to determine the amount of therapeutic agency it is capable of exerting. At any rate, it seems reasonable to suppose that if, by this means, the congestion of the capillaries could be removed, the tumefied pulp would be reduced to its natural size, and be relieved from the pressure to which, as a consequence of its distended condition, it is subjected. To obtain the largest amount of benefit capable of being derived from the operation, the puncture should be made in that portion where one of the principal arteries would be most likely to be punctured, and this, it seems to us, would be just where the canal of the root enters the chamber of the crown of the tooth. But in making the puncture here, the pulp being very small at this point, there is danger of cutting it off, and as reunion would scarcely be likely to take place, the portion in the central cavity would necessarily perish.

If the pulp were exposed, there would be a better opportunity of relieving the congested condition of its capillaries by the abstraction of blood, but the difficulty of obtaining free access to the organ by drilling a hole through the intervening dentine is so great, the tooth, when suffering from inflammation, being usually so sore to the touch that the slightest pressure is productive of great pain, hence, the operation will seldom if ever prove successful. Unless, therefore, the retention of the tooth is a matter of more than ordinary importance, it is better to remove it at once. But if it is an incisor or cuspid, the pulp should be immediately extirpated or arsenious acid applied for the destruction of its vitality; or, if suppuration has previously taken place, an opening should be made into the chamber of the

tooth as before directed, for the escape of the matter. Should it be found, after this has escaped, that disorganization has not extended to every part of the pulp, the remaining portion may be destroyed in the manner as above described. This done, the pulp-cavity and root, as soon as the inflammation of the socket has completely subsided, may be filled.

It will be seen from the foregoing remarks, that it is only at its very inception, that there is any chance of combating successfully acute inflammation of the pulp of a tooth, and even then, so rapid is the progress of the disease, it may baffle the best directed and most energetic treatment, that can be adopted. It may be that when attention shall have become more generally directed to the subject, that some more successful method of treatment may be discovered, but that a complete mastery over the disease will ever be obtained, is not to be expected.

But inflammation of the dental pulp is not always acute ; it sometimes assumes a chronic and local form. This often occurs where the chamber of a tooth has become gradually exposed by caries of the dentine, and when this happens, the action of the fluids of the mouth, and other foreign substances which obtain access to the cavity, as well as the decomposed portions of the tooth substance, cause an increase of vascular action in the exposed part, followed, very often, by a slight discharge, but the morbid action thus induced is, comparatively, seldom accompanied by pain. The pulp may remain thus partially exposed for months, and even years, without causing any other inconvenience than a momentary twinge of pain when some hard substance is accidentally introduced into the cavity of the tooth, which subsides immediately after its removal. Sooner or later, however, the pain thus excited will become more permanent, continuing each time it is produced, from five or ten minutes to one or more hours after the cause of the irritation has been removed. If a tooth be filled under such circumstances, the pressure of the fluid upon the pulp, which is

poured out from its exposed surface beneath the plug, will give rise to a more general and active form of inflammatory action.

The liability of the tooth to ache increases as the pulp becomes more and more exposed by the gradual decomposition of the dentine, and the inflammation may ultimately assume a more active form, or the pulp may become the seat of fungous growth, or be absorbed or destroyed by ulceration, or gangrene and mortification. Cases sometimes occur in which the disease is attended with severe darting pains, occurring very often, several times in the space of two or three minutes, succeeded by intervals of perfect ease for as many hours. At other times it is attended by dull aching pain, aggravated by taking sweet or acid substances into the mouth. In cases of this sort, the application of heating or stimulating substances to the exposed surface of the pulp will usually procure relief. Permanent exemption from pain, however, is rarely obtained, and sooner or later, it becomes necessary either to destroy the pulp or to extract the tooth.

The body of the pulp when the organ becomes exposed from a decayed opening in the grinding surface of a molar, is sometimes absorbed, while the prolongations in the roots often remain unchanged for two, three or more years.

Chronic inflammation of an exposed surface of the pulp, when long continued sometimes give rise to *ulceration*—a disorganizing process, which often causes the destruction of a large portion of the part occupying the central chamber of the crown of the tooth, making in it numerous little excavations. The ulcerated surface usually presents a yellowish appearance, and when the disorganizing process is arrested before it has effected the destruction of a very large portion of the pulp, usually becomes covered with healthy granulations.

When the inflammation occurs in cachectic individuals it often assumes an acute form, and sometimes terminates in gangrene and mortification. The loss of vitality may be

confined to the body of the pulp, or it may extend to every part of the organ. In the former case the pain continues, but in the latter it ceases as soon as mortification takes place. When this happens, the entire pulp, which has now a dark brown or black color, may be removed. But this is not a very common termination.

The symptoms of chronic as well as acute inflammation are always modified by the state of the general health, habit of body, and the temperament of the individual. The pain attending the former, however, is periodical, occurring at irregular and uncertain intervals, and constitutes that variety of tooth-ache so often relieved by local applications, whereas, in the latter, it is constant.

In chronic inflammation, the pulp is either actually exposed or only covered by decomposed or partially decomposed dentine, and the diseased surface, rarely embraces a larger circumference than that described by the bottom of the decayed cavity. The inflammation, therefore, is local as well as chronic, but, nevertheless, it is often of so persistent a character, as to render its removal exceedingly difficult. The dentist, however, is not so much restricted in the application of remedies as in the treatment of acute inflammation, and to the action of which it yields more readily. But notwithstanding all this, he will necessarily encounter difficulties in his efforts to subdue it. A greater length of time is sometimes required than the patient is willing to give, and the opening through the crown to the central cavity is, not unfrequently, too small, previously to the removal of the partially decomposed dentine, to admit of the direct application of the necessary remedial agent to the inflamed surface of the pulp. Again, it often happens, that the situation of the tooth and cavity are such as to prevent him from obtaining a complete view of the diseased part, and it is important that he should do this to enable him to determine whether the inflamed surface is ulcerated, or pours out a serous fluid, or whether the morbid condition consists merely of irritation, produced by the presence of acrid mat-

ter, or of partially or wholly decomposed dentine. Unless his diagnosis is correct, his prescription will be as likely to do harm as good. But, having ascertained the exact character of the disease, he may often be able to institute treatment that will result in the restoration of the pulp and the preservation of the tooth.

It is important, too, to understand the part which nature plays in the curative process, for cure here, as in the case of the cure of disease in other parts of the body, is effected by that internal force, which, as Chomel says, "presides over all the phenomena of life, contends unremittingly with physical and chemical laws, receives the impression of deleterious agents, reacts against them and effects the resolution of disease." This vital force is sometimes efficiently exercised in the cure of disease in the pulp of a tooth, but more frequently in its prevention, as is shown by the gradual ossification of the organ in those cases where it would otherwise become exposed by mechanical or spontaneous abrasion of the solid structures which enclose it, and occasionally by the formation of secondary dentine upon its surface at a point towards which the caries is advancing. Nature, no doubt, would always provide in this way against the exposure of the pulp, if the occurrence was always preceded for a sufficient length of time to enable her to do so, by sufficient irritation or increase of vascular action in it to call her energies into operation. But the formation of osteo-dentine, which constitutes the protective wall of defence, is a tardy process, and as a general rule, proceeds more slowly than the caries in the tooth, which causes the exposure of the pulp. Besides it often happens that its approach is not announced by the slightest irritation, a condition necessary to the new formation, until it reaches the central cavity. At other times, the approach of the disease gives rise to too much irritation, a condition equally unfavorable to the dentinification of the pulp. Thus no protective covering being formed, it soon becomes exposed, when it is subjected to the action of such irritating agents as may chance to be brought

into contact with it. Hence, its liability to become the seat of chronic inflammation as well as other forms of diseased action.

If the disease is attended with pain, the removal of this should first claim attention, and this should be effected with as little delay as possible, otherwise the morbid action may extend to every part of the pulp and peridental membrane, and assume a more active and unmanageable form. If the pain is the result of irritation produced by the direct action of mechanical or chemical agents, the cavity in the tooth should at once be carefully freed from all extraneous substances and decomposed portions of dentine. This done, a dossil of raw cotton or lint, saturated with spirits of camphor, laudanum, sulphuric ether, chloroform, creosote, or some one of the essential oils may be applied. Immediate relief is sometimes obtained by an application of this sort. Counter-irritants have sometimes been used with advantage. The pain has often been removed by exciting increased secretion of saliva, but when a sialagogue is used, the cavity in the tooth should be filled with raw cotton or lint to prevent the agent from being brought in contact with the exposed surface of the pulp. But a remedy which will relieve the pain in one case often aggravates it in another.

When the irritation is produced by acidulated buccal fluids, the application of carbonate of soda or some other alkali, will often give immediate temporary relief, but as the condition of the secretions of the mouth, especially of the salivary, is usually owing to gastric derangement, the correction of this constitutes the first and most important remedial indication. When any application is made to the pulp for the purpose of removing irritation and pain, their full effect will not be obtained unless the fluids of the mouth are excluded from the cavity of the tooth, and this may be done by closing the orifice with softened wax or mastic, using the precaution not to force it in so far as to press the application previously made, upon the exposed pulp.

Until within the last three or four years, the writer did

not believe it possible to preserve the vitality of a tooth by filling, after the pulp had become the seat of chronic inflammation, but he is now convinced that it can be done in very many cases, but to effect which several weeks of preparatory treatment are often required.

SPONTANEOUS DISORGANIZATION.

The spontaneous destruction of the pulp of a tooth is an affection which seems to have been entirely overlooked by writers on dental pathology ; and, although it is one which rarely occurs, examples of it are met with sufficiently often to entitle it to a place among the diseases of the teeth. The first case which attracted the attention of the author occurred in 1836, and he has subsequently met with six or seven others ; in each of which, the disorganization had been carried on so insidiously, that neither the presence of disease nor structural alteration was suspected, until the teeth had assumed a dull brownish or bluish brown appearance. The death of the pulp had not been preceded in any of these cases by the slightest indication of inflammatory action. It had, apparently, resulted from want of sufficient vital energy to sustain the nutritive function.

The sockets of the affected teeth, in the cases which have fallen under the observation of the author, were, seemingly, in a healthy condition—a circumstance, which, when we take into consideration that the parts at the extremity of the roots were exposed to the action of the disorganized remains of the dental pulps, may appear somewhat strange. But this may have been owing, partly, to diminished excitability in the alveolo-dental periosteum, and, partly, to the smallness of the quantity, and the innoxious character of the matter contained in the central cavities of the teeth. The gums of that portion of the alveolar border occupied by the affected teeth, had a pale, grayish-purple appearance, but exhibited no indications of actual disease. They were as thin and their margins as distinctly festooned here as in any

other part of the mouth. In some of the cases too, the teeth had been in this condition for seven or eight years. On perforating the crowns, only a drop of dark brown matter, having but little odor and about the consistence of thin cream, escaped from the pulp-cavity of each.

In all the cases which the author has seen of this most remarkable affection, the loss of vitality had taken place previously to the twentieth year of age, and according to his observations upon the subject, it seldom confines itself to a single tooth, but occurs simultaneously in corresponding teeth. The pulps of several usually perish at about the same time. In the first case to which his attention was called, six had lost their vitality. The affection, too, seems to be principally confined to the incisors and cuspids, and sound teeth appear to be as subject to it as those which are carious.

Now, as the disorganization of the pulp, in cases of this sort, is not the result of inflammatory action, it must be dependent upon constitutional rather than local causes—upon some peculiar cachectic habit of body, in which the function of sanguinification is imperfectly performed. This inference, too, seems to be fully warranted by the appearance of the subjects in all the cases which the author has had an opportunity of examining. Each of whom was characterized by an extremely pale and slightly bloated aspect of countenance—indicating serous condition of blood.

The remedial indications in cases of this sort, are the same as in necrosis produced by inflammation and suppuration of the lining membrane and pulp.

FUNGOUS GROWTH.

The pulp of a tooth, when exposed by decay of the crown, sometimes becomes the seat of a fungous growth, constituting a small vascular tumor. These morbid growths sometimes attain the size of a large pea, completely filling the cavity made in the crown of the tooth by decay; at other

times they do not exceed that of a small elderberry. The former have little sensibility, and bleed freely from the slightest injury; the latter are less vascular, but are nearly as sensitive as the pulp in a healthy state.

It often happens that a fungous growth of the gum or dental periosteum, finding its way through an opening in the side of the neck or root of a decayed tooth, appears in the central cavity, and this is sometimes mistaken for a morbid growth of the pulp. Tumors of this sort usually grow very fast, and sometimes attain the size of a hickory nut. They are exceedingly vascular, bleeding profusely when wounded, and are soon reproduced after removal. The author has met with tumors of this kind which had originated in the alveolo-dental periosteum of the extremity of the root.

The remedial indication in such cases consists in the removal of the tooth. A cure cannot be effected by extirpating the morbid growth. The author has frequently removed them nearly to the extremity of the root, but they have always reappeared in a few days or weeks after the operation. But even if a return of the disease could be prevented, still the extraction of the tooth should be insisted on, as all teeth in which tumors of this sort are situated, are morbid irritants, and cannot remain without detriment to the health of the parts with which they are in immediate connection.

OSSIFICATION.

Allusion has been made, several times, in the course of this work, to the ossification of the dental pulp, as a means employed by nature to prevent the exposure of this most delicate and exquisitely sensitive structure. But examples of it are occasionally met with in teeth which have suffered no loss of substance, either from mechanical or spontaneous abrasion, or from the decay of the dentine. The occurrence, whatever may be the other circumstances under which it takes place, is evidently the result of the operation of an

established law of the economy, dependent upon moderate irritation and a slight increase of vascular action, and ossification having commenced, it usually goes on until every part of the pulp is converted into a substance analogous to, if not identical with, cementum. We infer then that when the pulp of a tooth becomes the seat of a sufficient amount of irritation, ossification must follow as a necessary consequence, but if the irritation be succeeded by active inflammation, a different result may be expected.

The irritation necessary to the ossification of the pulp of a tooth sometimes arises from constitutional causes, but in the majority of cases, it results from the action of local irritants, and most frequently, from impression of heat and cold, communicated through the conducting medium of a metallic filling or a thin layer of dentine.

During the ossification, a sensation is occasionally experienced in the tooth somewhat similar, though altogether less in degree, to that which attends the knitting of the fractured extremities of a broken bone. A numb, vibratory pain, barely perceptible, is felt passing through the tooth several times a day, but only lasting a second or two at a time. It is scarcely sufficient to occasion any annoyance, or to attract anything more than momentary attention.

With the ossification of the pulp, the crown and inner walls of the root lose their vitality, but the appearance of the tooth is not, as in the case of necrosis arising from the disorganization of the pulp, materially affected. The central cavity being filled with semi-translucent bone, or osteo-dentine, the crown retains its natural color. The discoloration and opacity attending necrosis produced by other causes, results, partly from the presence of putrid matter in the pulp-cavity, and partly from its absorption by the surrounding dentinal walls.

INFLAMMATION OF THE DENTAL PERIOSTEUM.

Inflammation of the periosteum of a tooth may be *acute* or *chronic*, and each variety may be modified in its character

both by the state of the constitutional health and the causes concerned in its production. The acute variety, when left to itself, usually terminates in alveolar abscess, but the suppurative process sometimes extends to nearly every part of the periosteum, causing the entire death of a tooth, and often followed by erosion of the root, and necrosis of the alveolus. (See Fig. 142.) When favored by a cachectic habit of body, it often extends to the periosteum of the jaw, followed by suppuration and necrosis. Some idea may be formed of the severity which it occasionally assumes by the following case.

In 1840, a poor girl, aged fourteen, was brought to the author. About three months before, she had been taken to a barber tooth-drawer for the purpose of having the first left inferior molar extracted. The crown was broken off, the roots left in the socket. Inflammation supervened. This soon extended to the periosteum of the entire bone from the

FIG. 142.

second bicuspid to the coronoid process, and as it was permitted to run its course uninterrupted, it terminated in necrosis and exfoliation of all this portion of the bone, the anterior extremity of which, at the time she was brought to

the author, had passed through the integuments of the lower part of the face, and protruded externally. A few days after, it was removed without difficulty. See Fig. 142.

But, as the causes, symptoms and remedial indications of acute inflammation of the dental periosteum were briefly described in the chapter on tooth-ache, and as we shall have occasion to refer to the subject again when we come to treat of alveolar abscess, it will not be necessary to dwell upon it here. We will merely state, however, that, after having terminated in suppuration, it sometimes, instead of subsiding altogether, degenerates into a chronic form, and when fa-

vored by some constitutional vice, as the scorbutic, venereal or scrofulous, it often gives rise to the destruction of the socket and loss of the tooth.

Chronic inflammation of the dental periosteum, however, is not always preceded by a more active form of disease. It may assume this form at the commencement, but in this case it is complicated with tumefaction of the gums and discharge of puriform matter from between their edges and the necks of the teeth. For the treatment of this variety, the reader is referred to chronic inflammation and tumefaction of the gums.

CHAPTER TWENTY - FIRST .

DISLOCATION OF THE LOWER JAW.

FROM the peculiar manner in which the inferior maxilla is articulated to the temporal bones, it is not very liable to be dislocated, and when one or both of its condyles are displaced, the luxation is always forwards. The confirmation of the parts prevents it from taking place in any other direction. The oblong, rounded head of each condyle is received into the fore part of a deep fossa in the temporal bone, situated just before the meatus auditorius externus, and under the beginning of the zygomatic arch. The articular surface of each is covered with a smooth cartilage, and between which there is a movable cartilage. This latter is connected with the articulating surface of the condyle and fossa of the temporal bone by ligaments attached to its edges. But the articulation is rendered still more secure by means of an external ligament which rises from the external edge of the fossa in the temporal bone, and is attached to the neck of the condyle of the jaw, which it surrounds—constituting the capsular ligament. The intervening movable cartilage, from being more strongly connected with the head of the condyle than to the articular cavity, escapes with the former, whenever dislocation of the jaw takes place.

Dislocation of the lower jaw is rarely caused by a blow, except it is given when the mouth is open; it is more frequently occasioned by yawning or laughing. It has been known to occur in the extraction of teeth, and in attempting to bite a very large substance. Sir Astley Cooper mentions the case of a boy who had his jaw dislocated by suddenly putting an apple into his mouth to keep it from a playfellow.

After the jaw has been dislocated once, it will ever after be more liable to this accident, and in consequence of which Mr. Fox very properly recommends to those to whom it has once happened, the precaution of supporting the jaw whenever the mouth is opened very widely in gaping, or for the purpose of having a tooth extracted. But none of these causes would be sufficient to produce the accident, except the ligaments of the temporo-maxillary articulation are very loose, and the muscles of the jaw very much relaxed.

The author has never had an opportunity, in his own practice, of witnessing but one case of dislocation of the lower jaw, and the subject of this was a young lady from Virginia, about seventeen years of age. It occurred in attempting to extract the first right inferior molar. Both condyles were displaced, but so completely were the muscles of the jaw relaxed, that he immediately reduced it without the least difficulty, and afterwards, by supporting the jaw with his left hand, succeeded in removing the tooth.

When the lower jaw is dislocated, the mouth remains wide open, as seen in Fig. 143, and a great deal of pain is experienced, which, according to Boyer, is caused by the pressure of the condyles on the deep-seated temporal nerves, and those which go to the masseter muscles, situated at the roots of the zygomatic processes. The condyles having left their place of

FIG. 143.

articulation, are advanced before the articular eminences and lodged under the zygomatic arches. The jaw cannot be closed; the coronoid processes may be felt under the malar bones; the temporal, masseter and buccinator mus-

cles are extended; the articular cavities being empty, a hollow may be felt there; the saliva flows uninterruptedly from the mouth, and deglutition and speech are either wholly prevented, or very greatly impaired. Boyer says, that "during the first five days after the accident, the patient can neither speak nor swallow." The jaw, when only one condyle is displaced, is forced, more or less to one side.

If the dislocation continues for several days or weeks, the chin gradually approaches the upper jaw, and the patient slowly recovers the functions of speech and deglutition. We are told by Mr. Samuel Cooper, that it may prove fatal if it remains unreduced;* but Sir Astley Cooper says, he has never known any dangerous effects to result from this accident—on the contrary, that after it had continued for a considerable length of time, the jaw partially recovered its motion.†

In the reduction of dislocation of the lower jaw, the ancients employed two pieces of wood, which were introduced in each side of the mouth, between the molar teeth, and while they were made to act as levers for depressing the back part of the bone, the chin was raised by means of a bandage.

The method usually adopted by surgeons for reducing a dislocation of this bone, consists in introducing the thumbs, wrapped with a napkin or cloth, to prevent them from being hurt by the teeth, as far back upon the molars as possible, then depressing the back part of the jaw, and at the same time, raising the chin with the fingers. In this way the condyles are disengaged from under the zygomatic arches, and made to glide back into their articular cavities. But the moment the condyles are disengaged, the thumbs of the operator should be slipped outwards between the teeth and cheeks, as the action of the muscles, at this instant, in drawing the jaw back, causes it to close very suddenly, and

*. Vide Surgical Dictionary, p. 306.

† Vide A. Cooper on Dislocations, p. 389.*

with considerable force, so that this precaution is necessary to prevent being hurt, unless a piece of cork or soft wood has been previously placed between the teeth.

By the foregoing simple method of procedure, the dislocation may in almost every case, be readily reduced, but Mr. Fox mentions a case in which it failed. The subject was a lady who had had her lower jaw luxated several times before, and this time the accident was occasioned by an attempt which he made to extract one of the inferior dentes sapientiae. After having failed to reduce the luxated bone by the usual method, he says, he "happened to recollect a statement made to him by M. de Chemant, of his having been frequently applied to by a person at Paris, who was subject to this accident, and that he always succeeded in reducing the luxation immediately," by means "of a lever of wood, as recommended by Dr. Monroe." Profiting by this statement, Mr. F. procured a piece of wood "about an inch square, and ten or twelve inches long." He placed one end of this upon the lower molars, and then raised the other, so that the upper teeth aided as a fulcrum. As soon as the jaw was depressed, the condyle of the side upon which the wood was applied, immediately slipped back into its articular cavity. The wood was then applied to the opposite side of the jaw, and the other condyle reduced in the same manner.*

The method proposed by Sir Astley Cooper, consists, when both condyles are displaced, in introducing two corks behind the molars, and then elevating the chin. He, however, first places his patient in a recumbent posture.† But this is seldom necessary. The reduction of the dislocation can be as conveniently effected with the patient in a sitting as in a recumbent posture.

After the reduction of the dislocation, the patient is recommended to abstain for several days from the use of solid

* Vide American edition of Fox on the Human Teeth, p. 330.

† Vide A. Cooper on Dislocations, p. 391.

aliments, and to prevent a recurrence of the accident, to wear a four-tailed bandage,* or, what is still better, the bandage contrived by Mr. Fox, (see Fig. 70,) to prevent its recurrence in the extraction of teeth. When it is used for the latter purpose, the mouth is first opened to a proper extent, when, with the condyles in their articular cavities, it is applied, and the straps tightly buckled. This done, it is impossible to advance the jaw sufficiently to produce a dislocation.

PART FOURTH.

SALIVARY CALCULUS.

DISEASES OF THE GUMS AND ALVEOLAR PROCESSES,

AND THEIR TREATMENT.

PART FOURTH.

CHAPTER FIRST.

SALIVARY CALCULUS.

THE physical characteristics, and local and constitutional indications of salivary calculus, having been noticed in a preceding place, it will not be necessary to refer to them again. We shall, therefore, confine our remarks chiefly to its elementary constituents—its origin—the manner of its formation—its effects, and the removal of it from the teeth.

FIG. 144.

FIG. 145.

Tartar or salivary calculus sometimes accumulates in very large quantities, giving to the mouth a most disagreeable and repulsive aspect, and imparting to the breath, not unfrequently, an almost insufferably offensive odor. Fig. 144 represents a set of teeth encrusted with it, and Fig. 145 a single tooth, presented to the author by Dr. W. Allen, of Massachusetts, with the largest accumulation of this substance he has ever seen in one mass. Its longest diameter is an inch and an eighth, its shortest seven-eighths, and its

thickness five-eighths of an inch. Imbedded in its substance is the entire crown and neck of a lower *dens sapientæ*, which was removed with it. It is of a light brown color, and weighs two drachms and seventeen grains.

CHEMICAL CONSTITUENTS OF SALIVARY CALCULUS.

Salivary calculus is composed of phosphate of lime and animal matter, combined in various proportions, according as it is hard or soft, consequently no two analyses will yield the same result. The following is the analysis made by Mr Peps for Mr. Fox. Fifty parts yielded :

Phosphate of lime,	35
Fibrini, or cartilage,	9
Animal fat, or oil,	3
Loss,	3
	<hr/>
	50

Berzelius gives the following analysis. He found one hundred parts to contain

Phosphate of lime and magnesia,	79.0
Salivary mucus and salivine,	13.5
Animal matter,	7.5
	<hr/>

Dr. Dwinelle, dentist, of Cazenovia, New York, furnishes the following :

“Of one hundred parts, there are,” says he, “of

Phosphate of lime,	60
Carbonate of lime,	14
Animal matter and mucus,	16
Water and loss,	10
	<hr/>
	100”

The last named gentleman acknowledges that he could make no two analyses agree. Hard dry tartar contains more earthy, and less animal matter than the soft humid tartar.

The infusoria of which M. Mandl says tartar is composed, have their origin in the vitiated mucus which is always mixed with it. Scherer detected infusoria, with a microscope, in the saliva of a girl laboring under a scorbutic affection of the mouth, in large numbers, but the author is inclined to believe that they had their origin in the mucous secretions of this cavity, which are always mixed with the former fluid. They are more or less numerous, as the tartar is hard or soft, or in proportion to the quantity of mucus that enters into its composition.*

ORIGIN AND DEPOSITION OF SALIVARY CALCULUS.

There exists a variety of opinions with regard to the source from whence salivary calculus is derived. English and American writers believe it to be a deposit from the saliva, but the French do not agree concerning its origin. Jourdain thinks it is secreted by glands, which he believes to be scattered over the periosteum of the teeth. Gariot says it comes from the gums. Serres tells us he has discovered upon the mucous membrane of the gums, certain glands, whose particular function it is to secrete this substance. In commenting upon the views of this last mentioned author, M. Delabarre remarks: "The small glands, which he thus designates," (alluding to the appellation of *dental* which the author gives to them,) "may, perhaps, belong to the mucous or salivary system, for the saliva, as all physiologists know, is not alone furnished by the parotid glands, but by a great number of calculus kennels that are very observable in ruminating animals, scattered over various parts of the mucous membrane of the mouth. I, therefore, am of opinion that this is a gratuitous supposition on the

* Dr. Dwinelle gives a minute description of their appearance in the 1st No. of the 5th volume of the American Journal of Dental Science.

part of the author, because children of a very early age are not affected with tartar, and it is on them that he believes he has discovered the glands which produce it. Did these really exist, they would augment in size, instead of decreasing, as age advanced, and their functions becoming more and more established, they would attain to a very large size in old persons, and those most subject to tartar. Now, there is nothing to lead one to suppose their existence in these individuals. Therefore, to suppose that organs that have no functions may be very perceptible, which, when they have them, cannot be discovered, is contrary to sound philosophy; were we to do so in this case, the *dental glands* of the author would be entirely different from all others, which are the more decided the more they are in action. Inadmissible, then as this supposition is, I do not believe in the existence of these glands, which I have patiently searched for, but in vain."

Our own views in relation to the supposed existence of the dental glands of M. Serres, are so fully expressed in the foregoing remarks, that we do not deem it necessary to say more on the subject, except to add what has been suggested by others, that he has evidently mistaken the follicles of the mucous membrane of the gums for glands.

But M. Delabarre is not more fortunate in the theory which he advances of the origin of salivary calculus, than Serres. He believes it to be an exhalation from the mucous membrane of the gums. Alluding to what M. Dupuy, professor of the veterinary establishment at Alfont, says, concerning the formation of tubercular matter of a calcareous nature in soft tissues, where he supposes there are no other fluids but mucus, he tells us that it is "in the same manner that the exhalants of the gums furnish tartar," and that "they give out more or less of it according as the gums are in a healthy or inflamed state." "When diseased," he says, "they are covered with a whitish layer, which is at first soft," but gradually collecting upon the teeth, it afterwards becomes hard; and, according to this

author, it is only when the gums are inflamed that it is produced.

It is in this way that he accounts for its accumulation on the teeth of one side of the mouth, while those of the other have none of it on them, though they are all bathed alike in the saliva. The concretions of earthy salts in the salivary conduits, he accounts for, by supposing them to be furnished by the exhalants of the mucous membrane which lines them, and not by the fluid they convey to the mouth.

He accounts for analogous formations in other parts, in the same way. The calculous incrustations found upon a sound, on its removal, after having remained in the bladder for a long time, and from subjects in whom no previous disposition to gravel had existed, he supposes to be the result of irritation produced by the instrument, on the mucous membrane of this viscus. In replying to this part of his argument in support of his theory that salivary calculus is furnished by the exhalants of the mucous membrane of the mouth, Mr. Bell says, "The previous non-existence of calculus in the bladder cannot be deemed any proof that the elements of its composition had not been held in solution in the urine, requiring only the occurrence of any extraneous body in the bladder to serve as a nucleus for its deposition. This view of the subject is amply confirmed by the fact, that depositions, both of the lithic salts and of the triple phosphate, the bases of the usual varieties of urinary calculi, are constantly formed from the urine, after its expulsion from the bladder."

It is unfortunate for M. Delabarre, that he drew this analogy, for Mr. Bell has shown it to be conclusive against the theory which he intended to establish by it. He says, "that salivary calculus, or tartar of the mouth, is deposited in a similar manner from the saliva, is, I think, directly proved, or at least supported by the highest degree of probability by every circumstance connected with its formation." The fact, too, that it is always found in largest quantity on the teeth opposite the mouths of the salivary

ducts, is a strong argument of itself, in favor of the theory that it is a salivary formation; but, still more conclusive, is the fact of its formation within the very channels themselves of these conduits.

The theory of M. Delabarre is insufficient for the explanation of its deposition here, for, it is not presumable, that inflammation would seize upon a single point of the mucous membrane of one of these passages, without affecting it to a considerable extent. The most probable cause of its formation here, therefore, appears to us, to be the accidental precipitation of a particle of it from the saliva on its passage to the mouth, which, becoming entangled in the mucus, is detained, and afterwards serves as a nucleus for its deposition.

Of the existence of the elements of its composition in the saliva there can be no question. Chemical analyses of this fluid, direct from the glands, place all doubt upon the subject at rest. Turner, in enumerating its chemical constituents, mentions as one, bone earth,* and, Siedemann, Gmelin† and Scherer,‡ have detected phosphate of lime, as has also Enderlin§ and other chemists who have analyzed this fluid. Thus it is seen that the chief earthy constituents which enter into the formation of this substance are contained in the saliva. It may also exist in solution in the mucous fluid of the mouth.

The circumstance that its deposition on the teeth is always accompanied by inflammation of the gums, M. Delabarre seems to rely upon as conclusive in favor of the correctness of his views of the manner of its formation. But here again, he is equally unfortunate. The inflammation of which he speaks, is the effect, and not the cause, as he supposes, of its deposition. The soft white layer of tartar, of which he makes mention, as observable on the gums, when diseased, is nothing more than thick, hardened mucus.

* Turner's Chemistry, p. 756.

† Müller's Physiology, vol. 1, p. 461.

‡ French Lancet. April, 1845.

§ Liebig, Annalen, 1844, pp. 3 and 4.

We have repeatedly examined it, and are well assured of the correctness of the assertion.

The deposition of tartar on the teeth of one side of the mouth, without a similar deposit on the corresponding teeth of the opposite side, does not furnish the least shadow of evidence in support of the doctrine that it is an exhalation from the sanguineous capillaries of the mucous membrane of the gums. The mastication of food, with most persons, is principally performed by the teeth, on one side of the mouth, and, that this function prevents, in a considerable degree, the accumulation of tartar on the organs immediately concerned, is a fact with which every dentist must be familiar. Hence, its frequent collection on the teeth of one side, and not on those of the other. And, that it is ascribable to this circumstance, is susceptible of positive proof. If, on the removal of the tartar from the teeth of a person, in whose mouth it has only collected on those of one side, mastication be afterwards altogether performed on these, it will not re-accumulate on them, and if the requisite attention to the cleanliness of the teeth on the other side be not properly observed, it will soon collect there, although these teeth had before remained free from it.

Again, it often happens that disease of a severe character, is excited in the gums, by the use of mercurial medicines and other causes, and yet, but a small quantity of tartar collects on the teeth; but, that any condition of the general system, or of the mouth, tending to increase the viscosity of the fluids of this cavity, promotes its formation, is undeniable. There are, however, some temperaments much more favorable to its production than others, and, it is a fact equally well established, that the mucous membrane of those in whose mouths it accumulates in largest quantity are the most irritable, and their buccal fluids most viscid. Again, if it were deposited by the mucous fluids of the mouth, it would collect in largest quantities on those teeth which are less abundantly bathed in the saliva, as for example, the anterior surfaces of the upper incisors and cus-

pids, while those opposite to the mouths of the ducts, which discharge this fluid into the mouth, would be less liable to deposits of tartar than any of the other teeth.

From all the light, therefore, that has been thrown upon this subject, the conclusion that this earthy matter is chiefly a salivary deposit, appears to us irresistible, and the following seems to be the manner of its formation:

It is precipitated from the saliva, as this fluid enters the mouth, on the surfaces of the teeth, opposite the openings into the ducts, from which it is poured. To these, its particles become agglutinated by the mucus always found, in greater or less quantity, upon them. Particle after particle is afterwards deposited, until it sometimes accumulates in such quantities that nearly all the teeth are almost entirely encrusted in it. It is always, however, found in greatest abundance on the outer surfaces of the superior molars, and the inner surfaces of the inferior incisors, and it is opposite to these that the mouths of the salivary ducts open.

EFFECTS OF SALIVARY CALCULUS UPON THE TEETH, GUMS AND ALVEOLAR PROCESSES.

The effects arising from the presence of this substance on the teeth are always pernicious, though sometimes more so than others. An altered condition of the fluids of the mouth, diseased gums, and not unfrequently the gradual destruction of the alveolar processes, and the loosening and loss of the teeth, are among the consequences that result from it. But beside these, other effects are sometimes produced; among which may be enumerated: tumors and spongy excrescences of the gums, of various kinds; necrosis and exfoliation of the alveolar processes, and portions of the maxillary bones, hemorrhages of the gums, anorexia and derangement of the whole digestive apparatus; foul breath, catarrh, cough, diarrhea, diseases of various kinds in the maxillary antra and nose, pain in the ear, head-ache, melancholy, hypochondriasis, &c. The character of the effects,

however, both local and constitutional, depends upon the quantity and consistence of the tartar, and the temperament of the individual as well as the state of the general health; and the two former of these are determined by the two latter, and the attention paid to the cleanliness of the teeth. If this last be properly attended to, salivary calculus, no matter how great the constitutional tendency to its formation may be, will not collect in large quantity upon the teeth. The importance, therefore, of its constant observance, cannot be too strongly impressed upon the mind, and especially upon those in whom there exists a great tendency to its deposition.

The teeth and their contiguous parts suffer more from accumulations of this substance, than almost any other cause. Caries is not much more destructive to them.

When permitted to accumulate for any great length of time, the gums become so morbidly sensitive, that a tooth-brush cannot be used without producing pain: consequently, the cleanliness of the mouth is not attempted, and thus, no means being taken to prevent its formation, it accumulates with increased rapidity, until the teeth, one after another, and in quick succession, fall victims to its desolating ravages.

It sometimes not only undermines the soundest constitutions, by occasioning discharges of fetid matter from the gums, and corrupting the juices of the mouth, but it also renders the breath exceedingly unpleasant and offensive. So nauseating and disagreeable is the odor which some descriptions of tartar exhale, that the atmosphere of a whole room is contaminated by it in a few minutes.

MANNER OF REMOVING SALIVARY CALCULUS.

This is an operation of great importance to the health of the gums, alveolar processes and teeth. But from a misconception of its nature, rather than from fear of pain, many are much opposed to it: and notwithstanding the univer-

versal admiration in which clean and white teeth are held, suffer the beauty of these organs to be destroyed, rather than submit to its performance. There are some, indeed, who though scrupulously particular in everything that regards dress, seem, nevertheless, to consider the cleanliness of their mouths as unworthy of notice.

For the removal of tartar from the teeth, a variety of instruments are necessary, which should be so constructed, that they may be easily applied to every part of every tooth. The instruments put up in small boxes and sold in the shops, are illy suited for the purpose. Those used by dental practitioners are so very similar in their shape, and so well known, that we do not deem it necessary to point out the minute differences of construction, or even to give a general description of the instruments themselves.

Every dentist should have a sufficient number and variety to enable him to perform the operation in the most perfect manner, and with the least possible inconvenience to the patient.

If any particles of tartar be suffered to remain, they will irritate the gums, and serve as nuclei for immediate subsequent re-accumulations.

The adhesion of tartar to the teeth is sometimes so great, that considerable force is required for its removal, even when the sharpest and best tempered instruments are employed. But ordinarily it may be removed with ease. Considerable tact, however, is necessary to perform the operation in a skillful manner; more than most persons, from its simplicity, imagine. This skill can only be acquired by practice. Tartar may be taken from the outer and inner surfaces of the teeth without much difficulty, but the removal of it from between them, is more troublesome, and and can only be effected by means of very thin, sharp-pointed instruments.

Several sittings are sometimes necessary for the completion of the operation, especially when the tartar has accumulated in very large quantities. In cases of this sort, it should be

removed at the first sitting from between the edges of the gums, and the necks of the teeth. The mouth in the mean time, during the intervals between the several operations, should be gargled several times a day, with some cooling and astringent wash; but more particular directions will be given on this subject in the next chapter.

During the removal of tartar from the teeth, the gums often bleed very freely, and when much swollen and spongy, it may be well to promote it by holding tepid water in the mouth. When the lower incisors are loose, as is often the case, the operation should be proceeded with cautiously to prevent starting them from their sockets, and this is the more necessary when the tartar is very hard and adheres with great tenacity.

Chemical agents are sometimes employed for the removal of salivary calculus, especially such of the mineral acids as are supposed to have less affinity for the lime of the teeth, than the phosphoric with which it is combined; but it is scarcely necessary to say, that any acid capable of dissolving tartar, will act upon these organs. The use of agents of this sort, therefore, should be carefully avoided. Nearly all, both of the mineral and vegetable acids, as has been shown in a preceding part of this work, are prejudicial to the teeth.

CHAPTER SECOND.

DISEASES OF THE GUMS.

THE gums and alveolar processes, from apparently the same cause, frequently assume various morbid conditions. An unhealthy action in one, is almost certain to be followed by disease in the other. The most common form of disease to which these parts are subject, is usually, though very improperly, denominated scurvy, from its supposed resemblance to *scorbutus*, "a genus of disease in the class *cachexiæ*, and order *impetiginis*, of Cullen." To this disease, however, it bears no resemblance. Instead, therefore, of continuing the use of the term, we propose to treat it under the appellation of *chronic inflammation and tumefaction of the gums, attended by recession of their margins from the necks of the teeth* which seems to express more clearly the condition of the parts, and the nature of the disease. The gums sometimes, though less frequently, become the seat of acute inflammation. The other affections to which the gums are liable, will be noticed under their appropriate heads.

The diseases of the gums and alveolar processes, are divided by Mr. Bell, into two classes: "those which are the result of local irritation, and those which arise from constitutional causes."

But were it not for local irritation, the constitutional tendencies to disease, in these parts, would rarely manifest themselves; and on the other hand, were it not for constitutional tendencies, the effects of local irritation would seldom be of a serious character. "Thus," says Mr. B., "the same cause of irritation, which, in a healthy person, would occasion only a simple abscess, might, in a different constitu-

tion, result in ulceration of a decidedly cancerous type; and in others, in the production of fungous tumors, or the formation of scrofulous abscesses."

Each constitution has its own peculiar tendency, or in other words, is more favorable to the development of some forms of disease, than others, and this tendency is always increased or diminished, according as the functional operations of the body generally, are healthily or unhealthily performed. Thus, in an individual of a mucous habit, derangement of the digestive organs increases the tendency superinduced by it to certain forms of diseased action in particular organs, and in none more than the gums. A local irritant, which would not before have produced anything more than slight inflammation of the margins of the gums, would now give rise to turgidity and sponginess of their whole structure. The same, too, may be said with regard to a person of a scrofulous or scorbutic habit.

The susceptibility of the gums to the action of morbid irritants, is always increased by enfeeblement of the vital powers of the body. Hence, persons laboring under excessive grief, melancholy, or any other affection of the mind, or constitutional disease, tending to enervate the vital energies of the system, are exceedingly subject to inflammation, sponginess and ulceration of the gums. But, notwithstanding the increase of susceptibility which the gums derive from certain constitutional causes and states of the general health, these influences, in the majority of cases, may all be counteracted by a strict observance of the rules of dental hygiene; or, in other words, by constant and regular attention to the cleanliness of the teeth.

A local disease, situated in a remote part, often has the effect of diminishing the tendency in the gums to disease, but when, from its violence or long continuance, the general health becomes implicated, the susceptibility of these parts is augmented.

Although deriving the predisposition which they have to disease, from a specific, morbid constitutional tendency,

they, nevertheless, when diseased, contribute in no small degree to derange the whole organism. An unhealthy action here vitiates the fluids of the mouth, and renders them unfit for the purposes for which they are designed—hence, when these parts are restored to health, whether from the loss of the teeth, or the treatment to which they may have been subjected, the condition of the general health is always immediately improved.

Thus, while the susceptibility of the gums to morbid impressions is influenced by the state of the general health, the latter is equally influenced by the condition of the former. And, not only is a healthy condition of the gums essential to the general health but it is also essential to the health of the teeth and alveolar processes. From the intimate relationship that subsists between the former and latter, disease cannot exist in one, without, in some degree at least, affecting the other. Caries of the teeth, for example, often gives rise to inflammation of the gums and alveolo-dental periosteum; and, on the other hand, inflammation of these parts, vitiates the fluids of the mouth, and causes them to exert a deleterious action upon the teeth as well as upon other parts of the body.

ACUTE INFLAMMATION OF THE GUMS.

Acute inflammation of the gums, very frequently occurs in connection with stomatitis, or inflammation of the mucous membrane generally, of the buccal cavity, which appears under a great variety of forms; but in this case, the inflammatory action does not always extend to the subjacent fibro-cartilaginous structure, and the local disease is complicated with other disorders, the treatment of which comes more properly within the province of the medical than that of the dental practitioner. Acute ulitis, or active inflammation of the gums, properly speaking, is in most cases, a purely local disease, usually arising from the irritation of dentition, or as a consequence of periodontitis. It often extends to the

submaxillary glands and muscles of the face, attended by swelling and other morbid phenomena.

But as this form of inflammation of the gums is treated of in connection with other subjects, it will not be necessary to repeat what we have said elsewhere concerning it.

CHRONIC INFLAMMATION AND TUMEFACTION OF THE GUMS ATTENDED BY RECESSION OF THEIR MARGINS FROM THE TEETH.

The affection on which we are now about to treat has been variously designated. Jourdain and other French writers term it, in its more advanced stages, "*conjoined suppuration*," because it is then complicated with a discharge of purulent matter from between the edges of the gums and the necks of the teeth, and a gradual destruction of the alveolar processes. Dr. Koecker calls it the "*devastating process*," because it is attended by wasting of the gums and alveoli, but it is more frequently treated of under the appellation of "*scurvy*" than any other name.

Chronic inflammation of the gums may exist for years without being attended by suppuration, or recession of their margins from the necks of the teeth, but, sooner or later, according to the amount of local irritation and the state of the constitutional health and habit of body, these phenomena are developed. With the occurrence of inflammation the margins of the gums gradually lose their festooned appearance, become thick, spongy and rounded, and ultimately, on being pressed, purulent matter is discharged from between them and the necks of the teeth. Their sensibility is increased, and they bleed from the most trifling injury.

The diseased action usually develops itself, first, in the gums around the lower front teeth and the upper molars, opposite the mouths of the salivary ducts, and in the immediate vicinity of aching, decayed, dead, loose, or irregularly arranged teeth, or in the neighborhood of roots of teeth, and from thence it extends to the other teeth. The rapidity of

its progress depends on the age, state of the general health, temperament and habit of body of the individual, and the character of the local irritants which have given rise to it. It is always more rapid in persons addicted to the free use of spirituous liquors, and in individuals in whom there exists a scorbutic tendency, or who have suffered from a mercurial diathesis of the general system, or from venereal disease.

The inflammation may be confined to the gums of two or three teeth, or it may extend to the gums of all the teeth, in one or both jaws.

FIG. 146.

The gums, as the disease advances, begin to recede from the necks of the teeth, the alveoli to waste, and the teeth, as they lose their support, loosen and ultimately drop out. In Fig. 146 is represented a case in

which nearly one-half of the roots of the lower incisors have become exposed from this devastating process.

But the loss of the teeth, though it puts a stop to the local disease, is not the only bad effect that results from it. Constitutional symptoms often supervene; more vital organs become implicated, and the health of the general system is sometimes very seriously impaired. Hence, the improvement often observed in the general health, after the loss of the teeth, of persons whose mouths have for a long time been affected with this disease. No condition of the mouth has a greater tendency to deteriorate its secretions, and impair the function of mastication and digestion than the one now under consideration.

In forming an opinion of the injury likely to result from the disease, the dentist should be governed not only by the health and age of the patient, and the local causes concerned in its production, but he should also endeavor to ascertain whether it is connected with a constitutional

tendency, or is purely a local affection. Some have been led to believe, that the wasting of the gums and alveolar processes may sometimes take place without being connected with any special local, or constitutional cause; that it is identical with that process by which the teeth of aged persons are removed, and that when it occurs in persons not past the meridian of life, it is symptomatic of a sort of premature old age.

Mr. Bell, on this subject, remarks: "In forming a judgment upon a case of this description, however, and even on those in which the loss of substance is associated with more or less of diseased action, it is necessary to recollect that the teeth are generally removed in old age by this identical mode, namely, the destruction of their support, by the absorption of the gums and alveolar processes; and as this step towards general decay commences at very different periods in different constitutions, it may, doubtless, in many cases, even in persons not past the middle period of life, be considered as an indication of a sort of premature old age, or an anticipation, at least, of senile decay, as far as regards these parts of the body."

The loss of the teeth, from the wasting of the gums and alveolar processes, although occurring frequently in advanced life, is not a necessary consequence of senility, for we occasionally see persons of seventy, and even eighty years of age, whose teeth are as firmly fixed in their sockets and their gums as little impaired, as in individuals at twenty. We do not recollect ever to have seen a case of this sort in which there was not evidently some diseased action in the gums. But it is of little importance whether it be the result of old age, a constitutional tendency, functional derangement of some other part, or local irritation, since the consequences resulting from such loss are always the same.

The gums after having been once the seat of chronic inflammation, are ever after more susceptible to the action of morbid irritants.

CAUSES.

The immediate or exciting cause of inflammation of the gums, is local irritation, produced by salivary calculus, carious, dead, loose or aching teeth, or roots of teeth, or by teeth which occupy a wrong position, or that are crowded in their arrangement. It may also be produced by very hard teeth, which, in consequence of their density, possess only a very low degree of vitality. Cases of recession of the gums, in which only a slight inflammatory action exists, are frequently met with in individuals having teeth of this description. The cause of this can only be explained, by supposing a want of congeniality between the organs and the more sensitive and highly vitalized parts with which they are in immediate contact. The same thing is observed when the vitality of the teeth is weakened by age, which Mr. Bell regards as an indication of senile decay.

The secretions of the mouth, too, especially the mucus, are often rendered, by certain conditions of the general system, so acrid as to become a source of irritation to the gums.

Dr. Koecker, who has had the most ample opportunities of observing this affection in all its various forms, says, he has never seen a case of it in which tartar was not present. That this is so in a large majority of the cases, there is no question, but that it is in all, is certainly a mistake. The author has met with many, in which not the smallest deposit could be detected.

The disease attacks persons of all ages, ranks and conditions, and in every country, climate and nation. "I have observed," says Dr. Koecker, "the inhabitants of the most opposite countries, the Russians, the French, the Italians, the Spaniards, the Portuguese, the English, the African, the East and West Indians, and those of the United States, to be all more or less liable to it."

It is, however, more frequently met with in the lower than in the higher classes of society. Persons who pay no

attention to the cleanliness and health of their teeth are particularly subject to it. With sailors, and those who live principally on salt provisions, it is very common. "Persons of robust constitutions," says the author just quoted, "are much more liable to this affection of the gums, than those of delicate habits; and it shows itself in its worst forms, oftener after the age of thirty, than at any earlier period."

To the causes of irritation, which have already been enumerated, may be added, accumulations of extraneous matter on the teeth, and along the edges of the gums, exodontosis, artificial teeth badly inserted, or of improper material, and dental operations badly performed. The use of improper tooth-brushes and powders, especially charcoal, may be reckoned among its exciting causes. The irritability of the gums is sometimes increased by the use of acids; at other times it is diminished.

Every condition of the general system tending to increase the susceptibility of the gums to the action of local irritants, favors the production of the disease; and every thing that tends to induce such conditions, may be regarded as its predisposing cause; such as bilious and inflammatory fevers, the excessive use of mercurial medicines, venereal poison, intemperance and debauchery. Any deterioration of the fluids of the body is peculiarly conducive to it. Persons of cachectic habits are far more subject to it, and generally in its worst forms, than individuals in the enjoyment of good health.

Strumous individuals sometimes have an affection of the gums, which differs from the one just described in many respects. The gums, instead of being purple and swollen, are paler and harder than ordinary, and, on being pressed, discharge muco-purulent matter, of a dingy white color. They often remain in this condition for years, without appearing to undergo any structural alteration, or to affect the alveolar processes.

The last variety of disease of the gums, is principally

confined to persons who have very white teeth; it is much less likely to attack males than females; and has never, so far as we have been able to ascertain, been mentioned by any dental writer. Mr. Fox speaks of ulceration of the gums of scrofulous children; but that is of frequent occurrence, and is characterized by the usual phenomena of inflammation. This rarely occurs before the age of eighteen or twenty; and it seems to be the result of impaired nutrition. The gums exhibit no signs of inflammatory action; on the contrary, they are paler, less sensitive, and possessed of less warmth than usual. It is never attended with tumefaction nor by absorption, except in its advanced stages; whereas, the affection of which Mr. Fox speaks is always accompanied by both.

TREATMENT.

In the treatment of inflamed, spongy and ulcerated gums, the first thing claiming attention, is the removal of the exciting causes. If there are dead or loose teeth in the mouth, or teeth which from their position, act as mechanical irritants, they should be extracted at once. The remaining teeth should at the same time be freed from all depositions of tartar and other irritating foreign matter.

Dr. Koecker goes so far as to recommend the extraction of any molar tooth, particularly of the upper jaw, which has lost its antagonist, believing that a tooth under such circumstances is a source of irritation to the alveolo-dental periosteum and gums.

“In this manner,” says Dr. K., “the loss of one molar tooth, produces the destruction of its remaining antagonist. This is effected, however, after a struggle of nature, of very long duration, which always involve, in some degree, all the other teeth in a like diseased condition; it is necessary, therefore, to prevent this morbid condition, particularly

pernicious in this disease, by the extraction of the tooth, or any molar so situated."

Although a molar tooth, after having lost its antagonist, is sometimes a source of irritation, it may often remain with impunity. Its removal is necessary only when it acts as an irritant to the gums, and it may in a majority of cases be prevented from doing this by keeping it constantly clean.

It is essential in the treatment of the disease under consideration that a decided impression be made upon it at once; consequently no time should be lost in the removal of local exciting causes. "The advantage derived from this operation," (extraction of dead, loose or irritating teeth,) says Dr. Koecker, "would be either partly or wholly lost, were it performed at different periods." This observation has been verified by the author more than once. When he has been prevented by the timidity of his patient from extracting all the offending teeth, at the first sitting, he has always found the cure much retarded, and in some instances, almost entirely defeated.

The extraction of such teeth as it may be necessary to remove having been effected, Dr. Koecker thinks it better to wait ten or fifteen days before the tartar is removed. The author has never been able to discover any advantage from such delay; on the contrary, he regards it as important that as much as possible should be taken from the teeth at the same time. Several sittings, however, are often required for its complete removal.

The bleeding from the gums and sockets, occasioned by these several operations, should be promoted by frequently washing the mouth with warm water; and when the gums are much swollen, advantage will be derived from scarifying them freely every three or four days with a sharp lancet. This last operation is highly recommended by Messrs. Hunter, Fox and Bell, and indeed its good effects are so apparent, that it should never be neglected.

The cure may be hastened by washing the mouth several

times a day with some tonic and astringent lotion. The author has found the following to be very serviceable:

℞	Pul. nut gall,	ʒ ij.	/
	Orris root,	ʒ i.	ss
	Cort. cinchonæ,	ʒ ij.	/
	Infus. rosæ,	ʒ iv.	Misce. ℥

Mr. Fox says, great benefit is derived from the use of sea water, and he recommends it whenever it can be procured; adding, that if the gums be tender, it should be used warm. We are unable to speak of the merits of this remedy from experience, never having tried it. We have, in cases where there was much soreness and ulceration of the gums, prescribed the following:

℞	Sub boras soda,	ʒ ij.	
	Decoct. sage,	ʒ vj.	
	Honey,	ʒ i.	Misce.

As a wash for the mouth, Dr. Fitch recommends a decoction of the inner bark of green white oak, which we have found beneficial. The following are recommended by Dr. Koecker, as being very serviceable:

“Take of clarified honey, three ounces, and of vinegar, one ounce. This, diluted in the proportion of three table-spoonfuls to a pint of warm sage tea, or water, may be used frequently during the day.

“Take of clarified honey, and of the tincture of bark, two ounces each. Mix and dilute as above.

“Take of honey, and of the tincture of myrrh, two ounces each. Mix and use as above.

Mr. Bell recommends the following:

℞	Alumnæ,	ʒ ij.	
	Decoct. cinchonæ,		
	Infus. rosæ ā	ʒ ij.	Misce. Fiat lotis.

But when the last prescription is used, the mouth immediately after, should be thoroughly washed with water and a soft brush, to prevent the sulphuric acid of the alum from exercising a hurtful effect upon the teeth.

The pleasantest, and at the same time the most efficacious, lotion which the author has ever employed, is the following :

R Tannin,	℥ iss.
Pyrethrum,	℥ i.
Orris root,	℥ i.
Flor. benzoin,	℥ i.
Cinnamon,	℥ i.
Sub-borate of soda,	℥ i. ʒ i.
South American soap-tree bark,	℥ viij.
Sach. alb.	℔ i.
Ol. Gaultheria,	℥ ss.
Ess. peppermint,	℥ viij.
Alcohol,	℔ iij.
Aqua font.	℔ v.
Coccus cactus,	℥ iij.

Misce—digest for six days and filter.

If, notwithstanding the use of the means here recommended, matter still be discharged from around the necks of the teeth, and the gums continue spongy, and manifest no disposition to heal, their edges may be touched with a strong solution of the nitrate of silver. This will seldom fail to impart to them a healthy action. It may be used in the proportion of from three to twelve grains to one ounce of water. The most convenient mode of applying it, is with a camel's-hair pencil. Its use is recommended by Mr. Fox, and will often succeed, when other remedies fail. In those cases where the matter discharged from the edges of the gums has a nauseating and disagreeable odor, "a weak solution," says he, "is an excellent remedy for rendering the mouth sweet and comfortable;" but in using it in this

way, precaution is necessary to prevent it getting in the fauces, as, in this case, it will cause disagreeable nausea.

While the means here directed for the cure of the disease are being employed, a recurrence of its exciting causes must be studiously guarded against. Tartar and foreign matter of every kind, should be prevented from accumulating on the teeth, by a free and frequent use of a suitable brush and waxed floss silk, which until a healthy action be imparted to the gums, should be used at least five times a day; as, for example, immediately after rising in the morning, after each meal, and before retiring at night. The application of the brush may at first occasion some pain; but its use should, nevertheless, be persisted in; for, without it, all the other remedies will be of but little avail. The friction produced by it, besides keeping the teeth clean, is of great service to the gums in imparting to them a healthy action.

Treatment, different from that here described, is necessary for the form of disease, which we noticed, as being characterized by preternatural paleness, and discharge of muco-purulent matter, from between the edges of the gums and the necks of the teeth. In the first case of this disease, treated by the author, he directed astringent and detergent lotions to be used; but these did not produce the desired effect. Having been led from his observations in this case, to believe that the disease was connected with the state of the constitutional health, and was probably the result of a debilitated condition of the general system, he recommended in the next case, the use of tonics and free exercise in the open air. This course, though attended with evident improvement of the general health, seemed to be productive of no benefit to the gums. They still appeared debilitated, and on being pressed, discharged matter from beneath their edges. He advised a continuance of the tonics and exercise, and with a view of exciting inflammation, touched the edges of the gums with nitrate of silver. This had the desired effect, and, as he had anticipated, a new disease was substituted for the old one; for the cure of which, he di-

rected the mouth to be washed, five or six times a day, with sage tea, slightly impregnated with alum, and sweetened with honey, and at night and morning with salt water.

This treatment was perfectly successful. In about three weeks the gums assumed a healthy appearance, acquired their natural color, and the discharge of muco-purulent matter entirely ceased. He has since had occasion to treat several other cases, in all of which he adopted the same treatment, and with like success.

MORBID GROWTH OF THE GUMS.

The structural changes which take place in the gums, as a consequence of increased vascular action, are almost as various as are the constitutional tendencies of different individuals. Those characterizing the affection last noticed, consist, for the most part, in increased thickness and recession of their edges from the necks of the teeth; but in the one on which we are now about to treat, there is morbid growth which is sometimes so considerable, that it almost covers the crowns of the teeth, thus interfering very seriously with the function of mastication. When thus affected, the gums have a dark purple color, thick, smooth and rounded margins, and discharge almost constantly from their inner surface, a thin, purulent matter, which exhales an exceedingly offensive odor. They bleed profusely from the slightest injury, and are so sensitive that the pressure even of the lips is sometimes attended with pain. They are also affected with a peculiar itching sensation, which, at times, is a source of great annoyance.

The accompanying engraving will convey to the reader, a more correct idea of the appearance of the gums, when thus affected than any description which can be given. It will be perceived from this, that the morbid growth extends to the gums of all the teeth, as it usually does, when they become the seat of this variety of diseased action.

Among the local and constitutional effects arising from

FIG. 147.

the disease are, offensive breath, vitiated saliva, destruction of the alveoli, with loosening and ultimately loss of the teeth, impaired digestion, with all its disagreeable concomitants, enlargement of the tonsils and bronchitis, together with a long train of other morbid phenomena.

CAUSES.

The exciting cause of this peculiar affection is local irritation, produced by salivary calculus, dead, diseased or irregularly arranged teeth, but the character of the structural alteration is evidently determined by some cachectic habit of body or constitutional tendency. It often attacks the gums of individuals whose teeth are sound and well arranged, but the author has never met with a case in which tartar was not present, though, in some instances, the quantity was so small as almost to lead one to doubt whether it would have had much agency in the production of the disease. But the susceptibility of the gums to morbid impressions, in individuals liable to this affection, is usually so great, that an irritant, which, under other circumstances would scarcely excite an increase of vascular action, gives rise, in cases of this sort, to the rapid development of an aggravated form of disease.

TREATMENT.

The first thing to be attended to in the treatment of the disease, is the removal of all dead and such other teeth as may, in any way, irritate the gums. The morbid growth

should be next removed, by making a horizontal incision entirely through the diseased gums to the crowns of the teeth. This should be carried as far back as the morbid growth extends. After this, the gums should be freely scarified by passing a lancet between the teeth down to the alveoli, in order that the vessels may be completely divided, and discharge their accumulated blood. This should be repeated several times, and at intervals of four or five days. Meanwhile the mouth may be washed several times a day with some astringent and detergent lotion, and occasionally with a weak solution of nitrate of silver. The tartar should be removed as soon as the gums have sufficiently collapsed to admit of the operation.

The progress of the disease may be arrested, but a cure cannot be affected by mere local treatment. Particular attention should be paid to the regimen of the patient, and such general remedies prescribed as the peculiar nature of the case may indicate. Excesses and intemperance of every kind must be avoided. The diet should consist principally of vegetables. If animal food be used, it should consist of fresh meats, such as beef, mutton and fowls. Fruits and acid beverages, such as infusions of malt and vinegar, lime juice, spruce beer, &c., may be used with advantage.

The teeth should be kept perfectly and constantly clean. Not a particle of foreign matter should be permitted to remain between them or along the edges of the gums. The most scrupulous attention to this precaution is indispensably necessary. It constitutes one of the most important remedial indications.

MERCURIAL INFLAMMATION OF THE GUMS.

The frequently repeated introduction of mercury into the system, when taken in sufficient quantity, gives rise to the development of peculiar morbid phenomena in the gums and other parts of the mouth. The first indication of the specific action of this powerful medicinal agent upon the animal economy, consists in a slightly increased redness and tume-

faction of the free edges of the gums around the necks of the inferior incisors, while the investing mucous membrane of the adherent portion, a little lower down, often assumes a white color, owing to the opacity of the epithelium. These appearances are soon followed by increased secretion of saliva, a brassy or coppery taste, soreness of the teeth and gums, inflammation and swelling of the mucous membrane of the roof the mouth, fauces, cheeks and salivary glands, swelling of the tongue, with increased redness of its edges, and a peculiarly offensive odor of breath. In the meantime, the edges of the gums about the necks of the teeth swell and assume an increase of redness; the saliva becomes viscid and is secreted in such abundance as to flow from the mouth, and the movements of the jaws are attended with pain. The alveolo-dental periosteum is thickened, and the teeth raised from their sockets and loosened. A vesicular eruption sometimes appears, followed by ulceration and sloughing of the gums, and very frequently by necrosis of large portions of the alveolar processes and jaw-bones. We were shown a few years since, the entire alveolar border of both jaws, the necrosis and exfoliation of which had been occasioned by severe mercurial salivation, and we have frequently had occasion to remove portions both of the superior and inferior maxillary bones—the necrosis having been occasioned by the use of this medicine.

By the prudent administration of mercury, however, salivation may be induced, without causing the deplorable effects just described. But the specific action of this agent upon the constitution is always attended by more or less tumefaction and sponginess of the gums, and when once brought under its influence, however perfectly its effects may have subsided, they are ever after more susceptible to morbid impressions.

TREATMENT.

It is scarcely necessary to say, that until the use of the mineral is discontinued, it will be impossible to remove or

even counteract its effects upon the gums, but in mild cases these usually soon disappear after the action which it has produced on the general system has completely subsided. But when they continue spongy, the bowels should be kept open with saline aperients, the patient restricted to a fluid farinaceous diet, and the mouth gargled several times a day with demulcent decoctions and mild astringent lotions, to which it may sometimes be advisable to add a little laudanum. Washes made from chloride of soda or lime may be used to correct the excessive fetor of the breath.

After the action of the medicine upon the system has subsided and the disease assumed a chronic form, the gums, as directed by Mr. Thos. Bell, should be freely scarified by passing a lancet entirely through their substance between the teeth, and this operation should be repeated as often as every four or five days, until they are completely restored. The use of astringent washes should at the same time be continued, and if there are any teeth which, from the loss of their vitality, or from having become very much loosened by the partial destruction of their sockets, act as irritants, they should be removed.

When the gums have ulcerated, the application of a strong solution of sulphate of zinc or nitrate of silver with a camel's-hair pencil is recommended. Chomel, an eminent French physician, has employed with advantage, in cases of mercurial stomatitis, vapor baths.

ULCERATION OF THE GUMS OF CHILDREN, ATTENDED WITH EXFOLIATION OF THE ALVEOLAR PROCESSES.

The gums and alveolar processes of children are occasionally attacked by a very peculiar and most singular form of disease, and it occurs more frequently during the shedding of the temporary and the dentition of the permanent teeth, than at any other period of childhood. We have never known adults to be affected with it, and to the ordinary spongy, inflamed and ulcerated gums, it does not appear

to be at all analogous. It bears a much closer resemblance to *cancerum oris*, yet, in many particulars, it differs from this disease.

Among the symptoms which characterize the affection, are itching, ulceration and separation of the gums from the necks of the teeth and alveolar processes; there is, at first, a discharge of muco-purulent matter from between the gums and necks of the teeth, but this ultimately becomes ichorous and fetid. The teeth loosen, and the alveoli lose their vitality and exfoliate. Ulcers are formed in various parts of the mouth, the gums and lips assume a deep red or purple color. In the exfoliation of the alveolar processes, the temporary, and sometimes the crowns of the permanent teeth, are carried away. The skin, for the most part, is dry; the pulse small and quick, the bowels generally constipated, though sometimes there is diarrhea, and to these symptoms may be added lassitude and a disposition to sleep.

These may be regarded as the most prominent phenomena of the disease in its most aggravated form. When exfoliation of the alveolar processes takes place, the symptoms usually abate, and sometimes wholly disappear. Delabarre says, "among the great number of children that are brought to the orphan asylum, he has had frequent occasion to notice singular complications of the affection," which are modified according to the strength, "sex, and idiosyncrasies of the different subjects." The gums and lips, in some, he describes as being of a beautiful red color; in others, the lips are rosy and the gums pale, and sometimes very much swollen. He also enumerates among the symptoms, burning pain in the mucous membrane of the cheeks, ulceration, pain and swelling in the submaxillary glands.

In the majority of cases, the disease is confined to one jaw and to one side, though sometimes both are affected by it. The effects on the permanent teeth, in all the cases which have fallen under the notice of the author, were always injurious, though Delabarre says, if children reach the seventh or eighth year, they are not injured, except that

it causes them to be badly arranged, in consequence of the want of a proper development of the jaw.

The author from whom we have just quoted, enumerates among the symptoms of the most aggravated form of the disease, inordinate appetite, burning thirst, a small spot on the cheek, or about the lips, resembling an anthrax, which rapidly increases in size, turns black, separates, discharges an ichorous fluid, and its edges "roll themselves up like flesh exposed to the action of a brisk fire." The flesh separates from the face; the bones become exposed, hectic fever ensues, and in the course of fifteen or twenty days, death puts an end to the sufferings of the child. We are also informed by Delabarre, that this affection is more common among females than males, and that the bones of the jaw are so much softened that they may be easily cut with a knife.

C A U S E S .

The disease seems to be the result of general debility or defective nutrition and a cachectic habit of body. It never occurs among the wealthy, but is always confined to children of the poor and destitute, and so far as the author's observations extend, to those who reside in cellars or small and confined apartments. Children of scorbutic habits, too, seem to be the most subject to it. Delabarre, however, says he has met with it in children who appear robust, and in other respects well. Its "seat is in the organs of nutrition, and in the fluids that are conveyed to them." The disposition of body which gives rise to it, he mentions as being sometimes innate, and sometimes the result of suffering from want of proper nourishment. He does not think it arises from a distinct disturbance of any organ separately considered.

From the great debility of all the organs of the body, their functions are languidly and imperfectly performed. That the disease is determined by general enfeeblement of the functions of the body, there is, we think, little doubt;

but whether or not it would develop itself independently of any local cause, is a question which we do not feel ourselves able satisfactorily to answer. It is not at all improbable, however, that local irritants are the exciting cause, and we are the more inclined to this belief from the fact, that in all the cases which have fallen under our observation, the teeth were considerably decayed, and had previously given rise to pain, and in some, they were coated with tartar. While, therefore, the character of the affection is determined by some peculiar constitutional tendency and general enfeeblement of the vital powers of the body, it is not unlikely, that local irritation is the immediate cause of its development.

T R E A T M E N T .

As the treatment of this affection comes more immediately within the province of the medical than the dental practitioner, we shall not dwell long upon the subject.

The local treatment should consist of acidulated and astringent gargles, and a solution of the chloride of lime or soda. The ulcerated parts may be occasionally touched with a strong solution of the nitrate of silver, and Delabarre says, he has in some cases, derived great advantage from touching them with the actual cautery. As soon as the alveolar processes exfoliate, they should be removed. After this takes place, a cure, with suitable constitutional treatment, is generally speedily effected. This last may consist of mild alteratives, a generous nutritive diet, consisting of succulent vegetables; and in the absence of fever, tonics and exercise in the open air.

The author just quoted, with a view to arouse the vitality, says, he has "successfully employed the *juice of cruciferous plants, the guinea in powders,*" but with the last he unites opium, in order to diminish the action of the digestive apparatus. Counter-irritants, such as blisters, he employs when necessary to displace irritation of some interior organ.

ADHESION OF THE GUMS TO THE CHEEKS.

The gums and inner walls of the cheeks sometimes contract adhesions which interfere seriously with the functions of the mouth. The affection may be congenital, but in a majority of the cases it occurs subsequently to birth. The extent of the adhesion may be small, or it may occupy the gums of the entire alveolar border of one or both sides of the mouth, and of one or of both jaws. Desirabode relates the case of a young man, who, in consequence of a venereal ulcer, had his upper lip united to the gums of the four incisors in such a way as to form a sort of loop above the teeth, and which by the retraction of the lip, were caused to jut out.*

Adhesion of the gums to the cheeks or lips, results from ulceration of the contiguous structures, whether caused by constitutional disease or local lesions. But that it arises more frequently as a consequence of the immoderate use of mercury than from any other cause, is a universally admitted fact. The author has met with several cases, however, in which the affection had resulted from ulceration of the gums of necrosed temporary teeth, and of the corresponding wall of the cheek, caused by excoriation of the mucous membrane, produced by the sharp points of the protruding roots. But the extent of the union in cases of this sort, is never very considerable.

The proper remedial indication in a case of this kind, consists in separating the parts which have grown together with a sharp bistoury. This done, reunion should be prevented by keeping a piece of cotton or lint in the wound, until the process of cicatrization is completed.

* Author's translation of Desirabode's Complete Elements of the Science and Art of the Dentist, page 227.

CHAPTER FIFTH.

TUMORS AND EXCRESCENCES OF THE GUMS AND ALVEOLAR PROCESSES.

FROM the gums and alveolar processes, tumors and excrescences of various kinds are occasionally developed, varying in character, from a mere simple growth of the gums, to morbid productions of a fungoid, cartilaginous, bony or scirrhus nature.

Some are smooth, others rough, and sometimes covered with eroding ulcers; some are bulbous, with a broad base; others are attached by a mere peduncle; some are soft; others are hard: the growth of some is astonishingly rapid; that of others is so slow as to be scarcely perceptible: some are almost entirely destitute of blood vessels; others appear to be almost wholly composed of sanguiferous capillaries: some are nearly destitute of sensibility; others are so exquisitely sensitive, that the slightest touch produces great pain; and hence have been named, *noli me tangere*: some are nearly white; others have a grayish appearance: some retain the natural color of the gum; others are of a dark purple hue. Finally, some exists for years without being attended with any serious consequences, while others, in a few months, acquire so aggravated a character as to threaten the life of the patient.

C A U S E S .

Tumors of the gums seldom arise spontaneously, but are, in most instances, the result of local irritation, occasioned by the presence of tartar, decayed or dead teeth, or roots of

teeth, but the character which they assume is determined by the state of the constitutional health or habit of body. Hence their great variety. The same causes operating here as on other parts of the body often produce different effects. One that would give rise to the development of a simple morbid growth of the gums in a person of good health, might, in one affected with some constitutional vice or specific morbid tendency, give rise to a tumor of a fungoid, cartilaginous, bony, or scirrhus character.

It is thought by some that morbid productions of this sort are occasionally developed, independently of any local cause, but this opinion does not seem to be well founded, and we are disposed to believe that, if all the circumstances connected with the history of each case, especially the previous condition of the teeth, could be accurately ascertained, their cause might, in most instances, be traced to irritation of the gums, or alveolar membranes, produced by some unhealthy or crowded state of these organs, or to the presence of salivary calculus.

Mr. Liston, in his practical surgery, remarks: "Very many of the *tumors of the jaws* are traceable to faulty growth or position of the teeth, to diseases of their bodies, or to improperly conducted operations upon them." And, in speaking of tumors of the gums, he observes: "They are caused by decay of some part of one or more teeth, of the crown, neck, fang, or they may arise from their being crowded or misplaced." A crowded arrangement of the teeth, is always productive of more or less irritation to the alveolo-dental periosteum.

We do not, however, conceive it necessary to the production of tumors, that any of the causes here enumerated should exist at the time they make their appearance. The gums and alveoli having been once affected, are ever after more susceptible to morbid impressions. It is, therefore, quite probable that an unhealthy action is sometimes continued in them long after the cause that produced it ceases to exist; and that this, favored by a subsequent unhealthy

action of some other part, or of the system generally, determines their development. When we consider how often, and almost constantly, the gums and alveolar periosteum are exposed to irritation, from the causes just mentioned, we must admit, that this hypothesis is supported by a high degree of probability. No one we think, will pretend to deny, that the maxilla and gums suffer more from local irritation than any of the other parts of the body; and to this irritation, we are firmly persuaded most of their diseases are to be ascribed.

T R E A T M E N T .

The most common form of morbid growth met with in the mouth, is that which resembles in structure the gums, except that it is usually rather more vascular. This description of tumor is always the result of dental irritation, and usually disappears soon after the removal of the cause.

In 1828, the author was consulted by a gentleman who had a considerable enlargement of the gums, which had followed an attempt to extract the first superior molar of the left side. In the operation the two buccal roots were fractured and left in their sockets. For fifteen or twenty days after the accident, he experienced considerable pain, but at the expiration of this period, it had entirely subsided. About two months after, however, it was again experienced, and although the gum had grown over the roots, it was sore to the touch, and soon began to assume a bulbous form, gradually increasing in size, until at the expiration of twelve months, when we saw the patient, the tumor had attained the size of a black walnut, and was attached by a broad base. As it was situated immediately over the fractured roots left in the socket, we advised the removal of the tumor previously to attempting their extraction. To this he most positively refused, but readily consented to the removal of the roots.

In the performance of this operation, about one-third of

the base was cut away, and the remaining part of the tumor sloughed off in a few days.

Mr. Fox relates the case of a lady who had an enlargement of the gums that almost entirely filled up one side of her mouth. She first applied to Sir Astley Cooper, who sent her to Mr. F. to have several decayed roots, at the base of the tumor, extracted, before he should attempt its extirpation. The fangs being imbedded in the gums, the excrescence was much lacerated in their removal; afterwards it became placid, assumed a dark color, and in a short time sloughed off. Thus a perfect cure was effected without any other operation than that of the extraction of the decayed roots.

This tumor, it would seem, partook somewhat of a fungoid character, and excrescences of this description are usually more difficult to cure than those which consist of a mere simple growth of the gums, like the one first noticed. Although they sometimes disappear spontaneously, on the removal of the exciting cause, yet, in most cases, extirpation becomes necessary, and even this, when not performed in the most perfect manner, is not always successful. After the removal of one, another has been known to spring up in its place; and thus several have sometimes appeared in quick succession.

Mr. Hunter attributes the disposition of a tissue to reproduce excrescences of this kind, to a scirrhus tendency of the parts from which they originate, but a tumor will rarely re-appear, if the diseased structure be completely removed.

Mr. Fox recommends that excrescences of this sort should be extirpated by means of ligature, with the assurance that when thus removed, a second operation is seldom necessary. Excision is often attended with profuse and obstinate hemorrhage, and, on this account, the operation recommended by Mr. F. is, in most cases, preferable. The base of some tumors, however, is so broad, that a ligature cannot be applied sufficiently low to include the whole structure. In such cases we must resort to excision, and if the

hemorrhage cannot be stopped by compresses, the actual cautery may be employed.

Mr. Hunter in treating of morbid growths of soft parts, observes: "Arteries going to increased parts are themselves increased, and have not the contractile power of a sound artery;" hence when wounded, they bleed more freely than those that are in a healthy state."

The removal of excrescences of the gums by means of ligatures, not being attended with so much hemorrhage, and also usually exterminating them more effectually than excision, determined Mr. Fox in his choice of this mode of operating. In treating of this subject, he remarks: "I determined, some years since, that if any case of this kind should ever come under my care, I would attempt the removal by means of ligatures. The first case in which I was consulted, was a lady of about forty years of age, who had several of the teeth on the right side of the upper jaw extracted when she was a young woman; about five years before I saw her, the gums covering the jaw where the teeth had been situated, appeared to be thicker than before; they gradually increased in size until a very large tumor was formed; it had now become so large as to affect the speech, and, in other respects, was extremely troublesome.

"The lady was very desirous to have it removed; to effect which, without incurring the danger of hemorrhage, I employed ligatures, close to the jaw-bone, through the substance of the tumor, half of which was then included in each ligature. The ligatures were tied just tight enough to stop the circulation; the next day there was a great deal of inflammation, which subsided in proportion as the ligature began to produce ulceration, which, on the fourth day was very considerable; new ligatures were then applied; on the sixth day these were removed, and others introduced; on the eighth, one ligature came away, leaving the tumor hanging only by a small peduncle; this being cut through with a lancet, the whole was removed.

Even when the base is large, the tumor may be often suc-

cessfully removed by passing a needle, armed with a double ligature, through it, close to the bone, and tying it on each side sufficiently tight to cut off the circulation between it and the general system; and it should be reapplied as often as it comes away, until the tumor has sloughed off, when the place should be touched with diluted nitrous acid or with a solution of *nitrate of silver*.

Cartilaginous excrescences of the gums and alveolar processes are comparatively of rare occurrence, and are more difficult to remove than fungous tumors, or those which consist merely of a preternatural growth of the gums. The hardness of their substance is such, that, in many cases, their removal by ligature is impracticable, and extirpation with the knife is, also, sometimes, exceedingly difficult and tedious. Besides, the operation of excision is often followed by obstinate hemorrhage.

Ambrose Paré, with no small self-gratulation, talks of having removed them when they were so large that they came out of the mouth, giving a most hideous appearance to the face, and when no other surgeon dared to undertake their cure, because of the lividity of their color. "This lividity," says he, "I did not fear, but I had the boldness to cut and even to cauterize the tumors until the disease was entirely cured."*

Jourdain, in speaking of cartilaginous excrescences, remarks: "About thirty-six years ago, I was called, with Allertius Baringue, surgeon, to see a woman that had a tumor of a large size situated on the gum of the molar teeth. It occasioned her mouth to be drawn to the opposite side of her face when she was seized with spasms. We advised her not to delay too long in having it removed; to this she would not consent, but, in a short time, finding that the excrescence increased so fast, and in such a manner that it hindered her from taking food, she changed her mind. The tumor was embraced with a brass wire, which we tightened every day. The excrescence, receiving nothing now to aug-

* Lib. chap. viii, v. 1, p. 188.

ment its growth, fell, and, upon examination, we found that it was altogether cartilaginous.”*

Dr. Fitch quotes a case from Luzitanous, in which the operation for the removal of the tumor was followed by a fatal hemorrhage. The tumor is described as being about half the size of a hen's egg, exhaling a fetid odor, and being very painful. He also mentions a case of a somewhat similar character, that came under his own observation. “The tumor occupied the space of the four incisor teeth of the upper jaw. The teeth were all carious. I extracted them. The tumor had four fistulous openings, which ran in the direction of each tooth, and which furnished to each a fetid humor. With the actual cautery well heated in fire and double-edged, I made but one wound of the four fistulous openings; I touched the bone that was carious, which was repeated several times in the space of three months. In proportion as the exfoliations were made, the tumor diminished. The patient was cured near the end of the fourth month.”†

When the base of the tumor is very broad, and the bone beneath carious, as in the case described by Dr. Fitch, the actual cautery is, without doubt, the surest remedy, because it is obvious that until the diseased bone is exfoliated, a cure can never be effected. But under no circumstances is the use of it advisable.

Tumors originating in the alveolar processes or periosteum, are generally of an osteo-sarcomatous, or cartilaginous character. Their removal in either case is more difficult than that of fungous excrescence. The cure is also less certain.

Mr. Bell has given the history of two cases of tumors of the gums and alveolar processes. One of them, however, he says, had no connection with the alveolar processes, and the other succeeded to an attack of the tooth-ache which had lasted several months.

A case of osteo-sarcomatous tumor, occasioned by dis-

† Fitch's Dental Surgery, p. 237.

eased teeth, is recorded by Bordenave. Sir Astley Cooper gives the history of two cases of a like nature. In one the tumor originated in the alveolar cavities, and as it increased, displaced the teeth; in the other case the tumor was produced by diseased teeth. Dr. Gibson, also, mentions a case of osteo-sarcomatous tumor, which, "according to the patient's account, first appeared seven months before," (the time he first saw her,) "in the form of a small lump, seated in the gum above the canine tooth."

In the treatment of tumors originating from the gums, or alveolar processes, or from both, much depends on their character and the constitutional symptoms accompanying them. Some may be dispersed by simply extracting a decayed tooth or root; others will require extirpation, and, in some instances, even this will not avail. In short, the treatment must be varied to suit the respective circumstances of the case.

It sometimes happens, when an operation has been performed successfully, so far as regards the local disease, that the lungs, or some other vital organ, becomes affected. To prevent this, it is often necessary to get up, by means of a seton, artificial irritation in some neighboring part. Without this precaution, the life of the patient would often be put in as great danger as that from which it had escaped by the removal of the local disease.

On the extirpation of the fungous exostosis, or osteo-sarcoma, Sir Astley Cooper observes: "The operation, after constitutional means have been employed, and the continuance of these means after the operation, hold out the chief hopes of safety; for amputation without these, will do no more than avert the blow for a season."

These remarks will be found applicable to the treatment of the same description of disease, in whatever part of the body it may be situated. The constitutional symptoms should never be disregarded.

CHAPTER SIXTH.

ALVEOLAR ABSCESS.

As most of the phenomena attending the formation of alveolar abscess were noticed in the chapter on tooth-ache, it will not be necessary, in this place to dwell upon them at much length. The periosteum of a tooth having become the seat of acute inflammation, plastic lymph is effused at the extremity of the root. This is condensed into a sac or cyst, which closely embraces the root near its apex, and as suppuration takes place, pus is formed in its centre. The inflammation, in the meantime, having extended to the gums and neighboring parts, they swell and become painful, and as the pus accumulates in the sac, it distends and presses upon the surrounding walls of the alveolus, which by a sort of chemico-vital process, are gradually broken down. By this means, an opening is ultimately made through one side of the socket, when the pus, coming in contact with the investing soft structures, presses upon them and causes their absorption. Thus an outlet is effected for the escape of the accumulated matter.

The opening which gives egress to the pus, is usually in the gum opposite the extremity of the root, but the matter may escape from some other and more remote point. It may make for itself an opening through the cheek, or through the base of the lower jaw, and be discharged externally; or it may pass up into the maxillary sinus, or through the nasal plates of the superior maxilla, or form a passage between the two plates of the bone, and escape from the centre of the roof of the mouth.

The formation of abscess in the alveolus of an inferior

dens sapientiæ, is sometimes attended with inflammation and swelling of the tonsils and of the muscles of the cheek and neck. The author has known trismus to result from this cause.

The pain attending the formation of alveolar abscess, is deep seated, throbbing, and often so excruciating as to be almost insupportable. But as soon as suppuration takes place, it loses its severity, and with the escape of the pus ceases altogether, or very nearly, but the tooth, from the thickened condition of the alveolo-dental periosteum, particularly at the apex of the root, often remains sore and sensitive to the touch for several days. The energies of the disease, however, having been expended, the secretion of pus, in the majority of cases, wholly ceases, and the opening in the gums closes. But from the increased susceptibility in the alveolo-dental periosteum to morbid impression, occasioned by the presence of a tooth deprived of a very large portion, at least, of its vitality, a recurrence of the inflammation is liable to take place, when pus will be again formed and the passage for its escape re-established. But the pain attending any subsequent attack, is seldom so severe as in the first instance.

There are some cases, however, in which the inflammation, instead of subsiding altogether, degenerates into a chronic form. In this case, the sac at the extremity of the root continues to secrete pus, though the quantity is usually small, and the opening in the gums remains unclosed.

FIG. 148.

FIG. 149.

In the extraction of a tooth which has given rise to the formation of abscess, the sack is often brought away with it. Two teeth taken from the upper jaw, one a cuspid, and the other a first molar, are represented in the accompanying cuts, Figs. 148 and 149, where this had happened. In the case of the molar, the sac is attached

to the palatine root. Both of these teeth were extracted

previously to the formation of an external opening for the escape of the matter.

The time required for the formation of alveolar abscess, varies from three to ten or fifteen days, according to the violence of the inflammation. But a collection of pus may be detected by fluctuation under the finger, if applied to the tumefied gum, one or two days before an external opening is spontaneously formed for its escape.

The inflammation and pain attending the formation of abscess, in the socket of a tooth, often give rise to general febrile symptoms, headache and constipation of the bowels.

C A U S E S .

The immediate cause of alveolar abscess is inflammation of the alveolo-dental periosteum, and this may arise from inflammation and suppuration of the lining membrane and pulp, or from an accumulation of purulent matter at the extremity of the root, the egress of which, through the natural opening, having been prevented. It may also be produced by mechanical violence, or the irritation of a dead tooth.

T R E A T M E N T .

The treatment of alveolar abscess, should be preventive, rather than curative, for it rarely happens, after it has occurred, that the integrity of the parts is so perfectly restored, as to prevent a recurrence of the affection. Although the secretion of pus may cease for a time, and the opening in the gums become obliterated, the tooth being deprived of a large portion of its vitality, is liable, whenever the excitability of the alveolo-dental periosteum is increased by any derangement of the general system, to give rise to a recurrence of the disease. The formation of abscess, therefore, should, if possible, be prevented by the use of saline cathartics, the application of leeches to the gums, and a cooling

regimen. By prompt antiphlogistic treatment the inflammation may sometimes be arrested. But should these means fail to prevent the formation of pus, the tooth, unless its retention is called for by some peculiar necessity, should at once be removed. If, however, as is often the case, the patient will not submit to the operation, the escape of the pus through the gum should be promoted by warm fomentations to the mouth. As soon as fluctuation can be perceived by applying the finger to the tumefied gum, an opening may be made with a sharp lancet for the escape of the matter. After this has discharged itself, the swelling of the gums and neighboring parts soon subside.

The application of fomentations and emolient poultices externally, are rarely productive of any advantage, and may do harm by promoting the discharge of matter through the cheek or lower part of the face. When this occurs, a depression with puckering of the skin is apt to remain after the escape of pus through the opening ceases and the orifice has closed, causing disfiguration of the face. A very singular case of fistulous opening through the external integuments is mentioned by Mr. Thomas Bell. It had resulted from an abscess in the socket of the right inferior dens sapientiæ, and the discharge of matter had been kept up for two years before he saw the patient. "At this time," says Mr. B., "a funnel-shaped depression existed in the skin, which could be seen to the depth of nearly three-quarters of an inch, and a small probe could be passed through it into the sac of the abscess, underneath the root of the tooth. The abscess had now remained open for two years, during the latter of which, the parts had been in the state I have described. I removed the tooth, and as I anticipated, no farther secretion of pus took place; but so perfectly had the communication been established, that when the gum healed, it left by its contraction, a fistulous opening, through which a portion of any fluid received into the mouth passed readily to the outside of the cheek; and I could with care, introduce a fine probe completely through the passage. So free,

in fact was the communication, that some of the hairs of the whiskers, with which the external portion of the depression was filled, grew through the internal opening, and appeared in the mouth.

"I passed a very fine knife, resembling the couching needle, through it, and removed as perfectly as possible, a circular portion of the parietes of the tube towards the gum; but failed in this, and several other attempts, to produce a union. It was, therefore, resolved that the whole parietes of the depression should be removed, extending the incision as far internally as possible; and the integuments thus brought together as a simple wound. In consequence, however, of the suppuration of a small gland in the immediate neighborhood, the operation was deferred until that should have been dispersed, and it, therefore, remains at present in the state in which I have described it."

It rarely happens, however, that anything more is necessary for the cure of the external opening than the extraction of the tooth which had given rise to the formation of the abscess. The author has been consulted in many cases, and has never found it necessary to resort to other means, but should the external opening remain, the wall of the tube and depression may be removed in the manner as just described.

The formation of an abscess in the alveolus of a lower wisdom tooth, is sometimes productive of very serious and even alarming consequences. The following is one of several cases of the kind which have fallen under the observation of the author.

In 1832, he was sent for in great haste to visit a physician Dr. E., who resided thirty miles in the country. The doctor had been attacked two weeks before with severe pain in the left dens sapientiae of the lower jaw. At the expiration of three or four days, a physician was called in who made several unsuccessful attempts to extract the tooth.

The inflammation now extended rapidly to the fauces, tonsils and muscles of the jaw and face. Obstructed deglu-

tion and intractable fever soon supervened. Repeated blood-lettings, cathartics, and fomentations to the face were resorted to with little effect. His respiration was difficult and the muscles of his jaws soon became so rigid and firmly contracted that his mouth could not be opened.

This was the condition of the patient when the author first saw him, which was the morning of the day following the one on which he was sent for. In addition to the treatment which had previously been pursued, an injection with two grains of emetic tartar was administered. About seven o'clock in the evening, the fever was succeeded by alternate paroxysms of cold and heat. An effort was now made to force open his mouth, with a wooden wedge. This was partially successful, but his teeth could not be forced asunder sufficiently to admit of the introduction of the smallest sized tooth-forceps. But while his jaws were thus partially separated, he attempted to swallow some warm tea; in the effort an abscess bursted and discharged nearly a table-spoonful of pus from his mouth, and it was supposed that double that quantity passed down into his stomach. This gave immediate relief, but it was not until about three o'clock in the afternoon of the next day that his jaws could be forced apart sufficiently to permit the extraction of the tooth which had caused the trouble. To the roots of this, which were united, there was a sac about the size of a large pea, filled with pus. The patient recovered rapidly, and in a few days was quite well.

The following is the most singular case of alveolar abscess which has ever fallen under the observation of the writer: The subject was a lady of about thirty years of age. She had been troubled with a dripping of pus from behind the curtain of the palate for about twelve months, and becoming somewhat alarmed at its continuance, she called the attention of her family physician, Prof. Bond, to it, who, after having carefully examined the case, endeavored to ascertain the place from whence the matter came. He soon satisfied himself that it was from the socket of a diseased tooth, and

after passing his finger around on the gums covering the superior alveolar border, discovered a protuberance over the root of each upper central incisor, nearly as large as a hazelnut. This tended to confirm the opinion which he had formed with regard to the place from whence the matter came, and he requested the writer to visit the lady with him, which he did on the following day. On examining the case he advised the immediate removal of the affected teeth, and the more strongly as they were found to be in a necrosed condition.

The lady readily consented to the operation, which was performed on the following day. The discharge of matter from behind the curtain of the palate immediately ceased, and the patient was thus relieved from an affection which had been a source of great annoyance. The pus from the abscess, in this case, instead of passing out through the nasal plates of the superior maxilla, passed back over the roof of the mouth, and escaped in the manner as described.”*

Since the publication of the fourth edition of this work, the author was consulted in a case of a similar character to the one last noticed. The pus, however, had escaped from the socket of a first superior molar, to about the centre of the palatine arch, thence passed up into the posterior nares and was discharged from behind the velum palati.

Inflammation of the investing membrane of the roots of an inferior dens sapientiæ may produce equally serious effects, without occasioning the formation of an abscess in the alveolus. The eruption of these teeth are, sometimes, attended with like consequences. The irritation has, in some instances, extended to the lungs and produced consumption.

The occurrence of alveolar abscess in the socket of a temporary tooth, is often followed by exfoliation of the sockets

* Vide addition by the author to American edition of “The Natural History and Diseases of the Human Teeth,” by Joseph Fox, pp. 282-3.

of several teeth, and sometimes of considerable portions of the jaw-bone, seriously injuring the rudiments of the permanent teeth, and sometimes causing their destruction. The author saw a case, a few years since, in which an abscess of the alveolus of the first lower temporary molar had occasioned exfoliation of the sockets of a cuspid and two molars. About one-half of the alveolar cells of the two bicuspid and the cuspid of the second set, were also exfoliated—thus leaving their imperfectly formed crowns entirely exposed.

When the inflammation of the alveolo-dental periosteum results from inflammation of the pulp and lining membrane, the formation of abscess may be prevented by the prompt destruction of the latter with arsenious acid, cobalt or chloride of zinc. If an attempt is to be made to secure the preservation of the tooth, this should be done, as the chances of success are always greater previously to the formation of an abscess than afterwards. But for a description of the method of procedure in a case of this kind, the reader is referred to the chapter on filling the pulp-cavities and roots of teeth.

CHAPTER SEVENTH.

NECROSIS AND EXFOLIATION OF THE ALVEOLAR PROCESSES.

THE alveolar processes, as well as other osseous structures, are liable to necrosis or loss of vitality. When their connection with the periosteum—the source from whence they derive their nourishment and vitality—is destroyed, death follows as a necessary consequence. The loss of vitality may be confined to the socket of a single tooth, but more frequently it extends to several, and sometimes to the entire alveolar border, occasionally including a part or the whole of the jaw. It may occur in either jaw, but it is more liable to take place in the lower than the upper. When confined to the alveoli, the dead part is never replaced with new bone, but examples are on record of the regeneration of a part, and even the whole of the lower jaw. It is, however, denied by some, that the loss of any portion of this bone is ever replaced with true osseous structure.

When one or more of the sockets of the teeth lose their vitality, nature exerts all her energies to separate the dead from the living bone, a process technically termed *exfoliation*, and is supposed by some to consist in a sort of suppurative inflammation, but there is good reason to believe it is effected by the action of a corrosive fluid poured out from the fungous granulations of the living bone in immediate contact with the necrosed part. During the process of exfoliation, thin acrid matter is discharged from one or more fistulous openings through the gums or from between them and the necks of the teeth, and this investing structure having lost its connection with the necrosed bone, becomes soft and

spongy, and assumes a dark purple appearance. It is preternaturally sensitive to the touch, and bleeds from the most trifling injury.

In the admirable work of Mr. Fox, on the Natural History and Diseases of the Teeth, there are two engravings of exfoliated alveolar processes.

The first represents the alveoli of a central and lateral incisor and that of the left cuspid, with a portion of the maxilla, extending about five-eighths of an inch above the apex of the roots of the last mentioned tooth. The subject of this case was a gentleman whose left lateral incisor became carious; inflammation and pain ensued, together with swelling of the gums and lip. Instead of consulting a physician he applied poultices to his face, until suppuration in the alveolus took place, causing the formation of an external opening through the gums for the discharge of the matter. After his mouth had remained for some time in this condition, he applied to Mr. Fox, who, upon examination, found that not only the decayed tooth had become loose, but also one on each side of it. The first he extracted, and discovered that the alveolus, from the destruction of its periosteum, was quite rough. The adjoining teeth still continuing loose, were in a few weeks removed, and the slight force that was applied, brought with them the alveolar processes of the whole of the three teeth, and also a considerable portion of the jaw-bone. The other engraving represents an inferior molar and two bicuspid, with their sockets and a very large piece of jaw-bone. The necrosis and exfoliation in this case, as in the other, was produced by alveolar abscess.

The author has met with several very similar cases, though all were not produced by the same cause, and he has several specimens in his possession, two of which were presented him by his late brother, Dr. John Harris.

Since the publication of the fourth edition of this work, the author has met with two cases of necrosis and exfoliation of the alveolar processes, which are worthy of special

notice. The subject of the first case, was a gentleman of a strumous habit, about thirty years of age, and the necrosis and exfoliation extended to the sockets of all the teeth in the upper jaw. In May, 1851, he had the nerve destroyed in the second bicuspid, on the right side of the superior maxillary. We believe it was afterwards removed, and the pulp-cavity and root filled. About six weeks after, as nearly as we could ascertain, the socket of the tooth became slightly painful, but as his suffering was not constant, he supposed it would soon cease. The pain ultimately, however, began to increase, and by the latter part of the following September was so severe, and attended by so much constitutional disturbance, he was induced to consult a physician. After having been under medical treatment for about two weeks, the author was requested by the medical attendant to see him. The affected tooth was found upon examination, to be loose, and its socket in a necrosed condition. Inflammation had extended to every part of the alveolar border; the gums were very much swollen, and nearly all the teeth sensitive to the touch. As the patient was laboring under considerable cerebral derangement, and as no advantage could be derived from the removal of the tooth at this time, it was deemed advisable to let it remain until exfoliation of the necrosed socket should take place.

Without going into a detailed description of the local and constitutional treatment which was subsequently pursued, it will be sufficient to state, that necrosis extended to the sockets of all the other teeth, except those of the second and third molars on each side of the mouth. In the course of about two months, twelve teeth, together with their exfoliated sockets, and several large pieces of the maxillary bone were removed. It was hoped the disease would stop here, but in three or four weeks, the four remaining molars became very sore to the touch, and as purulent matter began to be discharged from their sockets, it became necessary to remove them. Several small pieces of bone were exfoliated after the last operation, but at the expiration of about four

months from this time, his mouth was sufficiently restored to enable him to wear a temporary set of artificial teeth.

The subject of the second case was a lady of a chacheetic habit, about thirty-five years of age. The necrosis resulted from inflammation of the alveolo-dental periosteum, occasioned by irritation produced by the roots of the four upper incisors, upon which artificial teeth had been placed. These,

FIG. 150.

however, had been removed some two or three weeks before the author saw the patient. At this time the necrosis had extended not only to the sockets of these teeth, but also up to the nasal crest of the maxillary bone, and the process of exfoliation had already proceeded so far that he was enabled to remove the entire piece—the appearance of which is represented in Fig. 150. In July, 1852, a few weeks after the removal of this piece, he again saw the patient, and on examination, found a large portion of the palatine plate of the bone in a necrosed state but the process of separation had not yet proceeded far enough to enable him to remove it.

The accompanying engraving, made from a drawing furnished the author by Dr. Maynard, of Washington City, represents a case of necrosis and exfoliation of a por-

FIG. 151.

tion of the outer wall of the alveolar ridge, and, as a consequence, the protrusion of the roots of the teeth on one side of the mouth. Dr. M. says, the only facts which he has been able to procure in relation to this case, "are contained in the patient's statement, 'that in 1818 he took a cold, which settled in his upper jaw, and a large piece of the jawbone came away.' The cast," says Dr. M., "from which the drawing was made, was taken in 1840—at which time I cut off the apices of several fangs which projected from the gums.

CAUSES.

The immediate cause of necrosis is the death of the periosteum, occasioned by inflammation. The causes of this, as has already been shown, are, in a large majority of the cases, dental irritation. Necrosis of the alveolar processes occurs very frequently while the system is under the influence of mercurial medicines, and during bilious and inflammatory fevers, and certain other constitutional diseases, as syphilis, small pox, etc. It may also result from mechanical injuries.

TREATMENT.

In the treatment of cases of this kind, little can be done. As soon, however, as the dead portions of bone become separated from the living, and can be easily removed, they should be taken away with a pair of forceps. To correct the offensive odor, and disagreeable taste occasioned by the constant discharge of fetid matter, a wash of diluted chloride of soda, or of the tinct. of myrrh may be employed. For any other purpose than this, we have not been able to perceive that local applications were of much advantage. Should constitutional symptoms supervene, tonics and a generous diet may be recommended.

CHAPTER EIGHTH.

GRADUAL DESTRUCTION OF THE ALVEOLAR PROCESSES.

FIG. 152.

WHILE treating of inflammation and tumefaction of the gums, the author adverted to the wasting of the sockets of the teeth, and he then took occasion to express a doubt that such operation of the economy ever manifested itself in the absence of all local disease.

It is always accompanied by a slight increase of redness, tumefaction and ulatrophia or shrinking of the edges of the gums, but the diseased action here is so inconsiderable as to attract but little attention. It is also attend by a slight discharge of puriform matter from between the margins of the gums and the teeth, but the quantity is so small that it usually escapes observation. The alveolo-dental periosteum participates also in the diseased action, but this is so slightly affected that the teeth often remain quite firmly articulated after the wasting of their sockets has proceeded so far as to expose more than half of each of their roots. Indeed the affection is so closely allied to chronic inflammation and tumefaction of the gums as scarcely to deserve separate consideration.

The progress of the disease is usually so slow that from ten to fifteen or twenty years are required to affect very perceptibly the stability of the teeth in their sockets. The commencement of this destructive process is usually first observed around the cuspid teeth ; but sometimes it makes its

first appearance on the alveoli of the palatine roots of the first and second upper molars, and occasionally it goes on here for years before it affects the sockets of any of the other teeth.

The teeth after their roots have become partially exposed, as might naturally be supposed, are more susceptible to impressions of heat and cold and more easily affected by acids, but this is about the only manifest inconvenience experienced from the disease, until they begin to loosen in their sockets.

In Fig. 152 is represented a case in which the roots of the teeth have become considerably exposed by the gradual wasting of their sockets.

C A U S E S .

The cause of this peculiar affection has never been very satisfactorily explained. Some have supposed that, inasmuch as it occurs most frequently in persons of advanced age, that it results from a decline of the vital powers of the body, independently of local causes. But, as it is often met with in middle-aged persons whose constitutional health is unimpaired, we doubt the correctness of the opinion. The teeth, in all the cases which have come under our observation, whether in middle-aged or very old persons, indicated, whatever may have been the state of the general health at the time, an excellent innate constitution. In every instance these organs were possessed of great density, and this fact is particularly noticed by Mr. Fox, who says :

“In a majority of cases in which this disease occurs, the teeth are perfectly sound, and from numerous observations, we think we may venture to assert, that persons who have had several of their teeth affected with caries in the earlier part of life, are not liable to lose, by an absorption of their sockets, those which remain sound ; but, where the teeth have not been affected with caries in the early part of life, persons, as they approach fifty years of age, and often much

earlier, have their teeth become loose from absorption, or a wasting of the alveolar process."

Now it is evident that teeth endowed with the power of resisting the action of the causes of decay, to which all teeth are more or less exposed, to so late a period of life, must be possessed of extreme density, and necessarily, a correspondingly low degree of vitality. In view of this fact, we have been led to believe that the teeth themselves act, to some extent, as mechanical irritants to the more highly vitalized parts with which they are immediately connected, causing an increase of vascular action in the periosteum of the thin edges of the alveoli and margin of the gums. This abnormal condition cannot, we believe, be traced to any other cause, and the existence of it evidently gives rise to the secretion of purulent matter observed between the edges of the gums and teeth. But whether this be true or not, it is doubtless to the corrosive action of this purulent matter that the gradual destruction of the alveoli is attributable.

We were for a long time inclined to ascribe the increase of vascular action in the edges of the gums and alveolo-dental periosteum to irritation produced by the pressure of the teeth against the intermediary walls of the alveoli, but having met with many cases where the teeth were not crowded, we were induced to enter into a more thorough examination of the cause, and the foregoing is the only conclusion to which we have been able to arrive.

T R E A T M E N T .

From what has been said concerning the cause of this affection, it is obvious that a cure cannot be effected. The secretion of the purulent matter, upon the chemical action of which the destruction of the alveoli manifestly depends, being caused by disease in the alveolo-dental periosteum and edges of the gums, arising from the physical condition of the teeth, the most we can hope to accomplish is, to retard its progress. This can only be done by cleaning the teeth

frequently and thoroughly, using the precaution each time to remove the corrosive matter from between the edges of the gums and teeth. For this purpose a brush with elastic bristles should be used, and much benefit will be derived by passing floss silk several times a day up and down between the teeth.

CHAPTER NINTH.

DISPLACEMENT OF THE TEETH BY A DEPOSIT OF OSSEOUS MATTER IN THEIR SOCKETS.

A TOOTH is sometimes slowly forced from its place by a deposit of bony matter in the bottom or on the side of the socket. Two, or even three teeth may be gradually displaced by exostosis of the alveoli at the same time. The deposition usually proceeds so slowly that one or two years are required to effect a very perceptible change in the situation of a tooth. The upper central incisors are more frequently affected than any of the other teeth, and the osseous deposit occurs oftener at the bottom than on the sides of the alveoli. In the first case, the tooth is gradually forced from the socket, and in the other, it is either pressed against one of the adjoining teeth or out of the arch. Irregularity in the arrangement of the teeth, is, in this manner, sometimes produced, especially, when more than one socket is affected at the same time. The central incisors are sometimes forced apart; at other times they are forced against each other, and caused to overlap. The deposition of bone, however, being generally confined to the bottom of the sockets, the teeth are more frequently thrust from their alveolar cavities, and when this occurs with a person whose upper and lower teeth strike plumb upon each other, it occasions much inconvenience; for, the elongated tooth must either be thrown from the circle of the other teeth, or, by striking its antagonist, prevent the jaws from coming together.

CAUSES.

So little is known concerning the cause of exostosis of the sockets of the teeth, that it may seem almost useless to attempt an explanation of it. That it results from irritation of the lining membrane, is very generally believed, but the cause of this does not seem to be well understood. We have thought that it might sometimes be produced by pressure on the bottom of the alveolus, especially when the extremity is nearly as large as any other part of the root of the tooth. But the susceptibility of the lining membrane to morbid impressions may sometimes be so great that the pressure of of a very conical root may be sufficient to produce this effect, or, it may be produced by the pressure of a tooth which possesses only a very low degree of vitality. A diseased state of the gums can have no agency in the production of the exostosis, for it most frequently occurs in individuals whose gums are perfectly healthy: and if it were the result of any constitutional tendency, all the teeth would be as likely to be affected by it, as those we have mentioned.

TREATMENT.

When the exostosis is on the side of the alveolar cavity, the tooth cannot be restored to its natural position, but when it is in the bottom of the socket, the elongated organ may from time to time, as it is forced from the alveolus, be filed off even with the other teeth, but in doing this care should be taken not to jar it. This will remove the deformity and prevent its displacement by the antagonizing tooth. By this simple operation, repeated as occasion may require, it may be preserved for years, and rendered almost as useful as any of the other teeth.

PART FIFTH.

DISEASES OF THE MAXILLARY SINUS,

AND

THEIR TREATMENT.

PART FIFTH.

CHAPTER FIRST.

PRELIMINARY REMARKS.

It was not until the knowledge of anatomy had made considerable progress that the existence of this cavity was known. CASSERIUS, an anatomist of Padua, who flourished during the latter part of the sixteenth and early part of the seventeenth centuries, is supposed to have been the first to discover it; but no correct description of it was given until about the middle of the latter, and the credit of this belongs to NATHANIEL HIGHMORE, author of a treatise on anatomy, published in 1651.* Hence its name, "*antrum highmorianum*."

This cavity is subject to some of the most formidable and dangerous diseases the medical or surgical practitioner is ever called upon to treat; and yet there are few diseases incident to the human body, that have not received more attention from writers on pathology and therapeutics than these. Diseases are sometimes here met with, over which neither the surgeon nor physician can exercise any control, and whose progress is only arrested with that of the life of the unfortunate sufferer.

All of the diseases to which the antrum maxillare is subject, however, are not of so dangerous a character; some are very simple and easily cured, but, even those which are regarded as the least dangerous, and that yield most readily

* This work is entitled "Corporis Humani Perquisitio Anatomica."

to treatment, when instituted during their incipient or earlier stages, often, if neglected, or improperly treated, assume a new and so aggravated a form as to bid defiance to the skill both of the physician and surgeon. While, on the one hand, the most simple affections of this cavity, may, by neglect or improper treatment, ultimately become incurable; those on the other, which are considered the most malignant and dangerous from their inception, might, we have no doubt, by timely and judicious treatment, be effectually and radically removed.

The form which the disease puts on, is determined by the state of the constitutional health or some specific tendency of the general system, and we can readily imagine, that a cause which, in one person, would give rise to simple inflammation of the lining membrane, or mucous engorgement of the sinus, would, in another, produce an ill-conditioned ulcer, fungous hæmatodes, or osteo-sarcoma. Simple inflammation and mucous engorgement, not unfrequently cause caries and exfoliation of the surrounding osseous tissues, and, in some instances, even the destruction of the life of the patient.

The importance of early attention to the diseases of this cavity is, therefore, very apparent, and this is the more necessary, as it is often difficult, and sometimes even impossible, to determine the character of the malady, until it has progressed so far as to have involved, to a greater or less extent, the neighboring parts; when, if it has not become incurable, its removal is, at least, rendered less easy of accomplishment. It may be safely assumed, therefore, that in a very large majority of the cases of disease of the maxillary sinus, the danger to be apprehended arises more from neglect than any necessary fatal character of the malady, so that in forming a prognosis, the circumstances to be considered, are the state of the constitutional health, the progress made by the affection, and the nature of the injury inflicted by it upon the surrounding tissues. If the general health is not so much impaired as to prevent its

restoration by the employment of proper remedies, and the neighboring structures have not become implicated, the prognosis will be favorable; but if the functional operations of the body have become very much deranged, and the bones of the face and nose seriously affected, the combined resources both of medicine and surgery will prove unavailing.

In young and middle aged subjects of good constitutions, a morbid action may exist in the antrum for years, without giving rise to any alarming symptoms, while the same affection in another less healthy, would rapidly extend and degenerate into so malignant a form of disease as to threaten the speedy destruction of the life of the patient. Medical history abounds with examples of this kind, and they conclusively establish, that the state of the general health and habit of body, whatever may have been the primitive characteristics of the malady, ultimately determine its malignancy; and in the treatment of affections of this cavity, as well as other local diseases of the body, the condition of system should not be overlooked.

Independently of the danger arising from the local affection, diseases of the antrum are, for the most part, very loathsome, and subject the patient to great annoyance. They change the qualities of its secretions, and cause them to exhale a nauseating, fetid odor. This, in many instances, is almost insufferable to the patient, and when they are prevented from escaping through the natural opening into the nose, they pass through an artificial one formed by art, or effected by their own disorganizing qualities, through the cheek, alveolar border or palatine arch, always causing the patient great inconvenience.

The occurrence of disease in this cavity is often very insidious. It not unfrequently happens that it exists for weeks and even months before its existence is suspected—the slight uneasiness being attributed to some morbid condition of the teeth or gums, and the symptoms attendant upon one description of affection are often so similar to those that accompany another, that it is impossible to de-

termine its true character until it has made considerable progress.

The morbid affections of the maxillary sinus are, for the most part, similar to those of the nasal fossæ. There is, however, one form of disease which seems to be peculiar to this cavity, viz. mucous engorgement. DESCHAMPS mentions two, dropsy and purulent accumulations;* but the first of these, properly speaking, is never met with in this cavity, and authors who have enumerated it among its diseases, have evidently mistaken mucous engorgement for it. The fluids that accumulate here are of a mucous or mucopurulent character, except when they are the result of the disorganization of some of the surrounding parts; then they are sanious.

The most simple form of disease that occurs here, is inflammation of the lining membrane, and this in most instances may be said to precede all others. It often subsides spontaneously, but when it continues for a long time, is apt to become chronic, and may then give rise to other and more formidable kinds of disease. When unattended by any other morbid affection, either local or constitutional, it is easily cured.

A purulent condition of the fluids of the antrum is a common affection, but is seldom met with in persons of good constitutions. It seems to be dependent upon a bad habit of body and inflammation of the pituitary membrane of the sinus, which last arises more frequently from dental irritation than any other cause. This condition of the secretions, sometimes gives rise to caries and exfoliation of portions of the surrounding bone, and to fistulous ulcers; but when dependent upon no other local cause than simple inflammation of the mucous membrane, it is seldom that such effects result from it. When complicated with other morbid conditions of the cavity, they are not unfrequent.

All purulent conditions of the secretions of the pituitary membrane, are by some denominated abscess. The name,

* Vide *Traite des Maladies des Fosses Nazales et le leurs Sinus*; p. 226.

however, as is justly remarked by Mr. Thos. Bell, is improper. Abscess is a different affection, and seldom occurs here; yet, instances of it have been met with at the extremities of the roots of teeth which had perforated the sinus; and it sometimes happens that when an abscess is seated in the alveolus of a superior molar, the matter, instead of making for itself a passage through the socket of the tooth on either side, escapes into this cavity, and, finally, with its secretions, through the nasal opening. Mr. Bell describes a case of abscess seated in the upper part of the antrum; but this, and one other, are the only examples of the kind on record.

Ulceration of the lining membrane is an affection less frequently met with. It is rarely, if ever, idiopathic, but seems rather to be dependent upon some other local malady or some specific constitutional vice. Scorbutic and serofulous dispositions, and those affected with a venereal taint, are more liable to be affected with ulceration of this membrane than persons of sound constitutions. Consequently, it is seldom cured by local remedies alone. It is almost always complicated with fungi of the membrane and caries of the walls of the sinus, and when neglected, it sometimes takes on a cancerous form and becomes incurable.

The next form of disease is caries of its walls. This, though always complicated with one or more forms of diseased action, seems, nevertheless, to be worthy of separate consideration. Like ulceration of the lining membrane, it is an effect of some one or more other affections. It may result from accumulation of the secretions of the sinus, ulceration, or from tumors.

The occurrence of fungous and other kinds of tumor is less frequent than any of the preceding affections; yet this cavity is not exempt from them, and they constitute the most dangerous description of diseases to which the superior maxilla is subject. Although it is probable, in their incipient stage, they might in nearly every instance be radically removed, it is seldom they are cured after they have at-

tained a very large size, and implicated, to a considerable extent, the surrounding tissues. They have, however, been successfully extirpated even after they had acquired great volume, and implicated to such an extent the surrounding parts, as to have rendered necessary the removal of the whole of the superior maxillary bone. They usually grow with great rapidity, and when not completely removed, are soon reproduced.

Besides these, other varieties of disease are occasionally met with here; and the antrum is liable to injuries, from blows and other kinds of mechanical violence; from the introduction of insects and foreign bodies; but of these, it is not necessary to speak in this place, as they will hereafter come up for special consideration.

The diseases of the maxillary sinus, are supposed to be dependent upon certain specific constitutional vices, the obliteration of the opening of this cavity into the nose and to dental irritation. That all of these may, at times, be concerned in their production, is more than probable.

But actual disease rarely develops itself spontaneously as a consequence merely of a bad habit of body or constitutional vice. This does not amount to perceptible manifestations of disease; but only occasions an increase of susceptibility of the tissues to morbid impressions; and when an unhealthy action is once induced here, a more aggravated, and not unfrequently different form of disease, than that which would otherwise have been produced, occurs.

Thus it may be seen, that disease of the maxillary sinus is dependent upon some exciting cause, favored by some constitutional vice, for without this, no serious morbid effects would be produced; or if produced, they would be of a different and less aggravated character. Any disposition or vice of body, which weakens the vital energies of the system, increases the susceptibility, or rather *excitability* of all its parts—those of this cavity equally with the rest. There are various kinds which have this effect: as, for example, the scorbutic, scrofulous, venereal, mercurial, etc., each of

which may influence the character of the morbid action produced, in a manner peculiar to itself, or similar to that which might be exercised by another, and cause it to assume a greater or less degree of malignancy, according as the functional operations of the body generally are more or less enervated by it.

This seems to be the way in which a bad habit of body is capable of affecting the maxillary sinus. It is predisposing but not an exciting cause of disease; and it is important that this distinction should be borne in mind. The one should never be confounded with the other, because an error of this sort, might, and would, in many instances, lead to the adoption of incorrect views concerning the therapeutical indications of the disease.

The writer might enlarge upon this part of the subject, but it is not necessary to do so, inasmuch as he will have occasion to advert to it hereafter.

Inflammation and ulceration of the pituitary membrane of the nose sometimes extend themselves to the maxillary sinus, but a disease is not so frequently propagated from the nasal fossæ to this cavity, as the intimate relationship between the two, might lead one to suppose. It is seldom that both are affected at the same time. Hence we infer, that, although lined by one common membrane, the propagation of disease from one to the other, is a rare occurrence.

The obliteration of the opening of this cavity is sometimes caused by disease in the nose, and when this happens, is followed by mucous engorgement of the sinus, inflammation of the lining membrane, distension of the osseous walls, and not unfrequently by other and more complicated forms of disease. But the closing of this opening is oftener an effect than a cause of disease in this cavity, and it generally re-establishes itself without any assistance of art, after the cure of the affection which caused it.

If all the circumstances connected with the history of the diseases under consideration could be ascertained, we think it would be found that these affections are more frequently

induced by a morbid condition of the teeth, gums, and alveolar processes, than any other cause. There are no sources of irritation to which this cavity is so much, and so often exposed, as that of the dental organism. It is separated from the apices of the roots of the superior molars and bicuspid only by a very thin plate of bone, and is sometimes even penetrated by them, so that it could scarcely be otherwise, than that aggravated and protracted disease in the teeth and alveoli, should exert an unhealthy influence upon it. The pain occasioned by diseased teeth, is often very severe, sometimes almost excruciating, and inflammation in the alveolo-dental periosteum and gums, frequently extends itself to the whole of one side of the face. It could hardly be possible, therefore, for this cavity to escape. Alveolar abscess, and sometimes necrosis and exfoliation of the socket of the affected tooth, arise from the inflammation thus lighted up. It often happens, that the gums and alveolar periosteum are affected for years with chronic inflammation, and other morbid affections.

If, in addition to these facts, other proofs be necessary to establish the agency of dental and alveolar irritation in the production of disease in the maxillary sinus, they may be had. Many of the affections here met with, are often cured by the removal of diseased teeth after other remedies have been employed in vain, and that, without even perforating the antrum. This would not be the case, if the irritation did not arise as a consequence of it.

Most writers on these affections agree in ascribing them to a morbid condition of the teeth and alveoli. There are some, however, who, though they admit that dental irritation may, perhaps, occasionally give rise to them, seem, nevertheless, to attribute their occurrence, in the majority of instances, to other causes, such as irregular exposure to cold, blows upon the face, and certain constitutional diseases.

We shall now proceed to the consideration of the different affections of this cavity, under their respective and appropriate heads.

CHAPTER SECOND.

INFLAMMATION OF THE LINING MEMBRANE OF THE MAXILLARY SINUS.

INFLAMMATION, when not complicated with any other morbid affection, is the most simple form of disease to which the pituitary membrane of the antrum is subject. As it precedes and accompanies all others, it will be proper to offer a few remarks upon it, before entering upon the consideration of those of a more aggravated nature.

Inaccessible as it is here to most of the acrid and irritating agents to which it is exposed in the nasal fossæ and some other cavities of the body, it would rarely become the seat of inflammation, were it not for its proximity to the teeth and alveolar border, and simple inflammation rarely gives rise to any other form of diseased action, unless favored by some general morbid tendency; and it usually subsides spontaneously on the removal of the exciting cause. In good constitutions, it is less subject to inflammation, and consequently, to any other description of morbid action, than those in whom there exists some vice of body, or constitutional predisposition. Febrile and gastric affections, eruptive diseases, such as measles, small pox, etc., syphilis, and excessive and protracted use of mercurial medicines, a scorbutic or scrofulous diathesis of the general system, and, in short, everything that has a tendency to enervate the vital powers of the body, increases its irritability.

When in a healthy condition, it secretes a slightly glutinous, transparent and inodorous fluid, by which it is constantly lubricated, but inflammation changes the character of the secretions; it causes them to become vitiated; at

first, to be less abundant, afterwards, to be secreted in larger quantities than usual, to be more serous, and so acrid as sometimes to irritate the membrane of the nose, over which they pass after having escaped from the antrum. It also causes them to exhale an odor more or less offensive, according as the inflammation is severe or mild. It moreover gives rise to a thickening of the membrane, and sometimes to obliteration of the nasal opening. This last rarely occurs, but when it does happen, an accumulation of the secretions and other morbid phenomena, of which we shall hereafter treat, result from it as a necessary consequence.

If at any time during the continuance of the inflammation, the patient is attacked with severe constitutional disease, the local affection will be aggravated, and sometimes assume a different character.

The inflammation, when long continued, degenerates into a chronic form, and is sometimes kept up for several years, without giving rise to any other unpleasant effects than occasional paroxysms of dull and seemingly deep-seated pain in the face, and a vitiated condition of the fluids of this cavity. The slightly fetid odor which they exhale, ceases to be annoying or even perceptible to the patient, when he becomes accustomed to it.

S Y M P T O M S .

The symptoms of inflammation here, though not always precisely the same, are nevertheless, for the most part, very similar. They are severe, fixed, and deep-seated pain under the cheek, extending from the alveolar border to the lower part of the orbit, local heat, pulsation and sometimes fever. Beyer says these symptoms are not always present, and that inflammation may exist when it is not suspected. Other affections of the face and superior maxillary, may be mistaken for this, and this for others; but that inflammation should exist without being attended with pain or any other signs indicative of its presence, is scarcely probable.

Deschamps distinguishes the symptoms from those of other affections of this cavity, by a dull, heavy pain in the region of the sinus, which, he says, becomes sharp and lancinating, and extends from the alveolar arch to the frontal sinus. The disease goes on without interruption, increasing until the superior maxilla of the affected side is more or less involved. This malady, he tells us, cannot be confounded with any other, if there is no external visible cause; it differs, he says, from a retention of mucus, by being painful at the commencement, and by not being accompanied with swelling of the bones; he distinguishes it from polypus, as that causes no pain; and from cancer, which occasions pain of a different kind. "Suppuration and ulcers have peculiar signs which cannot be confounded with those of inflammation." Pain in the molar and bicuspid teeth, accompanied by a sense of fluctuation in the parts, he seems to regard as a very certain indication of inflammation, and, especially, when joined to the other symptoms. "If an external cause is discovered, it," he says, "will furnish a certain diagnosis;" he also mentions fever and head-ache as almost invariable accompaniments.

The inflammation, if not subdued by appropriate remedies, after having continued for a length of time, gradually assumes a chronic form; the pain then begins to diminish, and is less constant; it becomes more dull, and is principally confined to the region of the antrum. The teeth of the affected side cease to ache, or ache only at times, but still remain sensitive to the touch. The mucous membrane of the nostril next the diseased sinus, is often tender and slightly inflamed, and if the other nostril be closed in the morning, or after two or three hours sleep, by pressing upon it with the thumb or one of the fingers, and a violent expiration be made through this, a thin watery fluid, of a slightly fetid odor, will be discharged, and pain will be experienced in the region of this cavity.

CAUSES.

All morbid conditions of the teeth and gums, causing irritation in the alveolar periosteal tissue, may be regarded as among the most frequent of its exciting causes. Of the affections of the teeth that do this, caries, necrosis and exostosis may be mentioned; also, loose teeth, and the roots of such as have been either fractured in an attempt at extraction, or by a blow or fall, and left in their sockets; or that have remained after the destruction of their crowns by decay. It sometimes happens, too, that inflammation is excited in this membrane by fractured alveoli, but when an accident of this sort occurs, the detached portions of bone are generally soon thrown off by the economy, and the cause being removed, the inflammation immediately subsides. Not so with the roots of teeth. They often remain concealed in their sockets for years, unless removed by art. Nature, it is true, makes an effort to expel them from the jaw, but this is accomplished only by a slow and very tedious process, and not, in many instances, until they have given rise to some serious affection. But of the deleterious effects that result from roots of teeth in the alveoli, it is not necessary now to speak; as extraneous bodies, they are always productive of more or less irritation. We might also mention exposure to sudden transitions of temperature, and certain constitutional diseases, as among the causes which occasionally give rise to inflammation of this membrane.

TREATMENT.

The curative indications of inflammation of the lining membrane of the antrum are simple, and for the most part, similar to those of inflammation in other parts of the body. Bleeding from the arm, saline purgatives, and fomentations to the face, and other antiphlogistic measures may be resorted to with advantage. In many cases, great benefit will

be derived from the application of leeches to the cheek, as recommended by Mr. Thomas Bell. When the disease is dependent, as in most instances it is, upon an unhealthy condition of the alveolar processes, the first thing to be done is to remove all such teeth, or roots of teeth, as are productive of the least irritation, for while any local sources of irritation are permitted to remain, neither topical nor general bleeding, or any other treatment, will be of permanent advantage.

Simple inflammation of the lining membrane of the antrum, would be of little consequence, were it not that it is liable to give rise to other and more dangerous forms of disease, such for instance, as a purulent condition of its secretions, or engorgement. It should never, therefore, be permitted to continue, but be as speedily arrested as possible; and for the accomplishment of this, the means here pointed out, will, if timely and properly applied, be found fully adequate.

CHAPTER THIRD.

PURULENT CONDITION OF THE SECRETIONS AND ENGORGEMENT OF THE MAXILLARY SINUS.

A PURULENT condition of the secretions of the maxillary sinus and mucous engorgement are, indiscriminately, though very improperly, denominated by many writers on the affections of this cavity, abscess. To this, neither bears the slightest resemblance. Deschamps treats of the former under the name of suppuration, and the latter, dropsy. Of the first, he says, "if after the time the inflammation has passed, the surrounding parts cease to be painful, while the affection still continues to cause pain in the antrum, and the fever, though diminished, occurs at irregular intervals, and if the inflammation is followed by pulsating pain, we will have reason to suppose that an abscess has formed in the sinus; and all doubts will be removed, if, on the patient's inclining his head to the opposite side, matter is discharged into the nostrils, or if some tubercles are formed near the outer angle of the eye, or alveolar border, which last happens more frequently; and, finally, if the purulent matter, not finding any opening through which to evacuate itself, distends the sinus to such an extent as to form a tumor outwardly upon the cheek." In short, all the symptoms which he mentions as belonging to the disease, are those accompanying the one under consideration. The matter, he says, is of a "putrid serous consistency."

Bordenave has fallen into a similar error. He terms an altered state of these secretions, suppuration of the membrane, and says that inflammation is not necessary to it.

He seems to have confounded in alveolar abscess those cases where the matter, instead of discharging itself, as it ordinarily does, by an opening which it makes for its escape through the alveolus and gum into the mouth, passes into the antrum, with abscess of that cavity. Again, he asserts that the disease (suppuration as he calls it) may be independent of the surrounding parts, and although ordinarily implicated with an altered condition of them, he affirms, it is sometimes the effect of disease primarily seated in this cavity.*

There is no doubt that a purulent condition of the fluids of this cavity is often complicated with ulceration of the lining membrane, but that the affection is at all analogous to abscess or suppuration, its very nature and situation is sufficient to show its absurdity. "A reference to the structure of the antrum," says Mr. Bell, "would appear to be sufficient to point out the improbability, to say the least, of the occurrence of abscess in such a situation. That a mucous membrane covering, in a thin layer, the whole internal surface of such a cavity, should become the seat of all the consecutive steps of true abscess, is a statement bearing on the face of it an obvious absurdity."† Notwithstanding the seeming improbability of such an occurrence, and it is certainly one that very rarely happens, abscess does, nevertheless, sometimes develop itself in this cavity; but, it is a different affection altogether from that usually treated of under that name. We have already adverted to a case narrated by Mr. B., a description of which, we intend hereafter to give.

When complicated with ulceration of the mucous membrane—and it is probable that a purulent condition of its secretions, in most instances, is thus complicated—the affection is precisely analogous to ozena, and, by many of the older writers, is designated by that name. Mr. Bell describes it, and very properly too, as being similar to gon-

* Vide *Memoirs de l'Academie Royale de Chirurg.*, vol. 12, p. 8.

† *Anat. Phys. and Diseases of the Teeth*, p. 253.

orrhœa—both diseases equally consisting of an altered secretion; in the one, of the pituitary membrane, and in the other of the mucous lining of the urethra, which, in neither instance, possesses any of the characteristics of abscess, though the matter in both is purulent.*

It has been before stated that the obliteration of the nasal opening was more frequently an effect than a cause of disease in the maxillary sinus; it does, however, sometimes become closed from other causes than an unhealthy condition of this cavity, and when this happens, engorgement of the sinus is the inevitable consequence. The fluids thus accumulated are not always at first purulent. They may become so, by retention in the cavity, and, when the closing of the opening is the result of previous disease in the antrum, the secretions are more or less altered from the very first.

Accumulation of the secretions of the antrum, whether in a healthy or purulent state, is a source of irritation to the lining membrane, and the pressure which they ultimately exert upon the surrounding walls, causes a new form of diseased action to be set up, which not unfrequently involves all the bones of the face as well as those of the base of the cranium in disease. When prevented from escaping through the nasal opening, they eventually make a passage for their escape. This is sometimes effected through the cheek, at other times beneath it, just above the alveolar ridge, or through the palatine arch or alveoli by the sides of the roots of one or more of the teeth, and thus establish a fistula, from which fetid matter will be almost constantly discharged. From openings of this sort the matter is sometimes discharged for years, while the disease in the antrum, very frequently, does not seem to undergo any apparent change. At other times the membrane ulcerates and the bony walls become carious.

A purulent condition of the mucous fluids of this cavity,

* Anat. Phys. and Diseases of the Teeth, p. 254.

independently of caries of the bone, or even of simple fistulous openings, is an exceedingly troublesome and unpleasant affection. The odor from the matter is often very annoying even to the patient, and when the secretions are retained for some days in the sinus before they escape, the fœtor is almost insufferable.

In good constitutions, the secretions of the antrum are not so liable to become purulent, though they be confined for a long time in the cavity. It is only in scrofulous, scorbutic, or debilitated habits that they are liable to become thus altered. Inflammation of the lining membrane (the immediate or proximate cause) may exist for years without giving rise to it. The differences in the effects produced upon them and the surrounding parts, by inflammation, is owing to the differences in the state of the constitutional health of those affected with it.

Where a puriform state of the secretions is complicated with ulceration of the membrane, the matter will have mixed with it a greater or less quantity of flocculi, sometimes of so firm a consistence, as to block up the nasal opening, and prevent its exit. Mr. Thomas Bell says, he has seen more than one case in which a considerable accumulation had taken place in the antrum, accompanied by the usual indications of this affection, (muco-purulent engorgement of the sinus,) when a sudden discharge of the contents into the nose took place, "in consequence of the pressure having overcome the resistance which had thus been offered to its escape."* Cases of a very similar nature have fallen under our observation, the history of one of which will be given in the course of this chapter. The formation of these flocculi rarely cease, except with the cure of the ulcers of the membrane. They give rise to considerable irritation, and their presence always constitutes an obstacle to the cure. They are usually easily removed by injections.

The pituitary membrane of the antrum when in a healthy state, secretes, as we have before stated, a transparent,

* Vide Anat. Phys. and Diseases of the Teeth, p. 258.

slightly glutinous and inodorous fluid, poured out only insufficient quantity to lubricate the cavity. But when inflammation is excited in the membrane, its secretions soon become more abundant, and, at first thinner, afterwards thicker and more glutinous.* Their color and consistence are not always the same. Instead of being transparent, they sometimes have a dirty opaque appearance; at other times they assume a greenish, whitish or yellowish color, and in some instances they bear a considerable resemblance to pus, which has been conjectured, might be owing to supuration of some of the mucous follicles and a mixture of pus with its secretions. Mr. Thomas Bell, however, inclines to the opinion that it is attributable to an "alteration simply" of the secretions of the cavity. But their color and consistence are determined by the degree of inflammation, the length of time it has existed, the state of the health of the lining membrane, and that of the surrounding osseous walls, the egress which the matter has from the sinus and the general habit of the body.

Affections of this sort, are more common to young subjects than to middle aged, or persons in advanced life. An eminent French writer says, that of three individuals affected with dropsy (mucous engorgement) the oldest was not twenty years of age.†

SYMPTOMS.

The diagnoses of the several affections of the antrum are so much alike, that it is often difficult to distinguish those that belong to one from those attendant upon another. The symptoms of mucous engorgement and purulent accumulations, however, are generally such, as will enable the practitioner to distinguish, with considerable certainty, these from other affections. They are always preceded by inflam-

* Vide *Maladies Chirurgicale*, tom. vi, p. 140.

† Vide *Traite des Maladies Chirurgicales et des Operations qui leur conviennent*, tom. vi, p. 139.

mation of the lining membrane; a description of the symptoms of which, having already been given, need not be repeated. Omitting these, we at once proceed to mention those by which they are accompanied.

In speaking of the symptoms more particularly belonging to a purulent condition of the secretions of the antrum, Deschamps says, the affection may be distinguished by dull heavy pain, extending along the alveolar border. Upon this symptom alone, little reliance can be placed, as it is always present in chronic inflammation. In addition to this, he mentions the presence of decayed teeth, soreness in those that are sound, and on the patient's inclining his head to the side opposite the one affected, the discharge of fetid matter from the nose. These are very conclusive indications of purulent effusions in this cavity. Bordenave, after enumerating the symptoms indicative of inflammation, mentions the following as belonging to the affection of which we are now speaking, viz. dull and constant pain in the sinus, extending from the maxillary fossæ to the orbit; a discharge of fetid matter from the nose, when the patient inclines his head to the opposite side, or when the nose is blown from the nostril of the affected side.* These symptoms are mentioned by almost every writer upon the subject, as indicative of a purulent condition of the secretions of the maxillary sinus.

The symptoms of engorgement differ materially from those which denote simply a purulent condition of the mucous secretions. The pain, instead of being dull and heavy, as just described, becomes acute, and a distressing sense of fullness and weight is felt in the cheek, accompanied by redness and tumefaction of the integuments covering the antrum.† The nasal opening having become closed, the fluids of the cavity gradually accumulate until they fill it, when, finding no egress, they press upon and distend the surrounding osseous walls, causing those parts which are

* Vide *Memoirs de l'Academie Royale de Chirurgie*, 12mo, tom. 12, p. 10.

† Vide *Bell on the Teeth*, p. 256, see also *Maladies des Fosses Nazales*, p. 228.

the thinnest ultimately to give way. The effects are generally first observable anteriorly beneath the malar eminence, where a smooth hard tumor presents itself, covered with the mucous membrane of the mouth. But this is not always the point which first gives away, the sinus sometimes bursts into the orbit, at other times outwardly through the cheek, or through the palatine arch. The long continued pressure thus exerted upon the bony walls, often causes the destruction of their calcareous molecules, and softening of their tissues.

The tumor, which is at first hard, in a short time becomes so soft as readily to yield to pressure. A distention, Deschamps says, may be distinguished from other diseases that affect the skin or intermediate structure between it and the bone, by the uniformity or regularity of the tumor, its firmness at the commencement, the slowness with which it progresses, and, above all, by the natural appearance of the skin, and the absence of pain when pressure is made upon the tumor. Obliteration of the nasal opening, he says, may be suspected by the dryness of the nostril of the affected side, the mucous membrane of which becomes thickened, and the cavity contracted; inflammation and sponginess of the gums, loosening and sometimes, (in consequence of the destruction of their sockets,) displacement of the teeth, may also be mentioned as occasional accompaniments of engorgement.

CAUSES.

Inflammation of the mucous membrane, is the cause of a purulent condition of the secretions of the maxillary sinus, and this arises more frequently from alveolo-dental irritation than from any particular habit of body or constitutional disturbance. Engorgement results from the obliteration of the nasal opening, which, in the case of altered secretion, is usually caused by inflammation and thickening of the lining membrane.

T R E A T M E N T .

The curative indications of muco-purulent secretion and engorgement of the maxillary sinus are, 1st, if the nasal opening be closed, the evacuation of the retained matter; 2dly, the removal of all local and exciting causes of irritation; 3dly, and lastly, the restoration of the lining membrane.

For the fulfilment of the first, an opening must be made into the antrum, and this should be effected in that part which will afford the most easy exit to the retained matter; but as it regards the several methods that have been proposed for the accomplishment of this object, practitioners differ; and before we proceed further, it may not be amiss to notice some of the various methods that have been adopted.

Dr. Drake, an English anatomist, and author of a work entitled "*Anthropologia Nova*," has the credit of being the first to propose the perforation of the floor of the sinus, through the alveolus of one of the roots of a molar tooth. This method of procedure, however, is said by some to have been inserted into Drake's Anatomy by Dr. Cowper, an eminent anatomist and surgeon.* Having never seen any evidence touching the correctness of this conjecture, we suppose its truth is, probably, somewhat questionable. M. Günz says, the credit belongs to John Henry Meibomius, who, a long time before, proposed a very similar method of treating these affections.† Henry Meibomius, many years after the death of his father, John Henry, proposed, for the evacuation of accumulated fluids in the antrum, the extraction of one of several teeth.‡ But the perforation of the maxillary sinus through the alveolus of a molar tooth, is said not to be the most ancient method. Molinetti, as early as the year 1675, describes an opening made through the

* Heister's Surgery, note to chapter 72, p. 445.

† Vide Mem. de l'Acad. Royale de Chirurg. 12mo, vol. xii, p. 12.

‡ Vide Discurs. de Abscessibus Internis. Dresd., 1718, p. 114, and la Dissertation d'Gunz.

cheek into the antrum, the wall of which, after having been exposed by a crucial incision through the integuments covering it, was penetrated with a trephine. And the perforation of this cavity through the alveolus of a superior molar, is an operation which, according to Velpeau, was performed by Zwinger, a long time before it was made by Meibomius: and Vanuessen says, Ruysch extracted several molars and canterized their sockets, for the destruction of a polypus, until an opening was made into the antrum, large enough to admit the finger. Drake, according to Bordenave, seems, nevertheless, to be entitled to the credit of having been the first to perforate the maxillary sinus as above described. We are also informed by the same author that Cowper treated a case of maxillary ozena, which had caused a large quantity of ichorous, fetid matter, to be discharged through the nose, by extracting the first molar, and perforating the antrum through the alveolus with an instrument suited to the purpose.

It is not at all probable that Meibomius was the first to propose the perforation of the antrum in this way, for his researches were not published until 1718, twenty-one years after the publication of Drake's *System of Anatomy*, and, besides, he regarded the perforation of this cavity as a dangerous operation, and, on that account, confined himself simply to the extraction of a tooth. Saint Yves, says Velpeau, treated with success a person affected with fistula, the floor of whose orbit had been destroyed by the removal of a tooth.

With regard to the tooth most proper to be extracted, authors differ. Cheseldon preferred the first or second molar, Junker recommends the extraction of the first or second bicuspid, and if a fistula had formed, to enlarge it instead of perforating the floor of the antrum. But the second molar, it being directly beneath the most dependent part of the cavity, is the most suitable tooth to be removed. If this be sound, the first molar, *dens sapientiae*, or either of the bicuspid, if carious, may be extracted in its stead, and

in fact, no tooth beneath the antrum, in an unhealthy condition, should be permitted to remain.

An opening having been effected through the alveolus of a tooth, into the antrum, it should be kept open until the health of the cavity is restored. For this purpose, sounds and bougies adapted to the purpose have been introduced. Heuerman recommends the employment of a small canula, which is also preferred by Bordenave and Ritchter, the latter of whom says, it should be kept closed to prevent particles of food from getting into the sinus. But whether a canula or bougie be introduced into the opening, it should be so secured as to prevent it from coming out or passing into the antrum. Deschamps recommends that it be fastened to one of the adjoining teeth by means of a silk or metallic ligature.

Lamorier, an eminent surgeon of Montpellier, recommended perforating the antrum immediately above the first molar, or rather between it and the malar bone. In this, he seems to have been influenced by the consideration that the wall of the cavity here, presents the least thickness, and that this is the most dependent part of the sinus. If a fistulous opening had previously formed in some other place in the mouth, he did not always deem it necessary to make another. His method of operating is as follows: The jaws being closed, the commissure of the lips are drawn outwards and slightly upwards with a curved instrument, called a speculum; this done, the gum is incised across the malar apophysis, or maxillo-labial sulcus, and the bone made bare, which is next pierced with a spear-pointed punch. The opening is afterwards enlarged if found necessary.

Desault is of the opinion that the opening should be made through the canine fossa, beneath the upper lip, and for that purpose, after having laid bare the bone, he employed a sharp triangular and a blunt pointed perforator, which he invented for the operation. Runge, says Velpeau, used nothing but a scalpel. Mr. Charles Bell invented a tre-

phine for that purpose, but this does not possess any advantage over the instruments employed by Desault and Runge. In case of fistula in the cheek from the antrum, Ruffel advises the insertion of a trocar, to be carried through the gum, so as to form a counter opening. Through this, in a case which he treated, he passed a seton, and it remained six weeks; at the expiration of this time, a cure was accomplished. This practice has been followed by Callisen, Zang, Busch, Henkle, Bertrandi, Faubert and others. Callisen is of the opinion that when the tumor points in the palatine arch and fluctuation is felt, the artificial opening should be formed there. Gooch, in a case which he treated, advised the perforation of the antrum through the nasal surface, and fixing in the opening a canula of lead. We are also informed by the same author, that Acrel, after having operated in the manner proposed by Cowper, inserted a second canula into the sinus through a fistulous opening formed in the nose. The method attributed to Weinhold, consists in penetrating the sinus from the upper and external part of the canine fossa, with the instrument directed obliquely downwards and outwards, so as to avoid the branches of the infra-orbital nerve; and then placing in the opening thus made a little lint. Weinhold directs, that when the antrum has no other opening, the instrument should be carried entirely through the palatine arch, and then by means of a curved needle and thread, he introduces a roll of lint, saturated or covered with some appropriate medicine, and this, he designs to act as a seton.

Velpeau says, the perforation is affected "in the point of election or of necessity. The first varies according to the ideas of the operator. The circumstances, on the contrary, determine the second. In cases of abscess, dropsy, fistula, and ulceration, the operation is almost always performed in the place of election. Then, provided one of the molar teeth to be unsound, it must be extracted, together with the adjoining tooth; the gum is then to be cut down to the bone, externally, internally, behind and before, forming a

kind of square flap, and to be completely detached from the surrounding tissues ; after this the alveolus are to be perforated with the instruments of Desault, and an opening made large enough to admit the finger into the sinus." For the evacuation simply of purulent mucus, or accumulated fluids, we believe with Boyer, that the opening should always be made from beneath ; and we are the more convinced of the importance of giving the alveolus of an extracted tooth the preference, from the consideration that it is to the irritation produced by some one or more of these organs, that the diseases of this cavity are attributable. Even though a fistula may have formed above the alveolar ridge, beneath the cheek, or in the palatine arch, we should not neglect to extract such teeth, whether carious or sound, as may be productive of irritation. It may not always in such cases be necessary to perforate the sinus from the socket of a tooth, though the cure in most instances, is expedited by it.

Jourdain, an eminent French dentist, and graduate in surgery, instead of seeking egress for matter accumulated in the maxillary sinus, by any of these methods, proposed, in a memoir presented to the Academy in 1765, to probe the cavity by its natural opening, and then by suitable injections to restore it to health. The Academy gave this proposition its attention ; it was carefully and minutely discussed. The practicability of obtaining entrance into the sinus in this way was called in question ; it was contended that the difficulties presented by the peculiar structure of the parts were such that they would seldom be overcome. The practice has been wholly abandoned.

When the natural opening is closed, the first indication, as has been stated, is the evacuation of the matter, and for this purpose, a perforation should be made into the sinus, and the most proper place for effecting this, it has been shown, is through the alveolar cavity of the second molar.* It may, however, be penetrated from that of either of the other molars or bicuspid.

* Vide Anat. Phys. and Diseases of the Teeth, p. 261.

The perforations, after the extraction of the tooth, is made with a straight trochar, which will be found more convenient than those usually employed for the purpose. The point of the instrument, after having been introduced into the alveolus, through which it is intended to make the opening, should be pressed against the bottom of the cavity in the direction towards the centre of the antrum. With the handle of the instrument in the hand of the operator, a few rotary motions will suffice to pierce the intervening plate of bone.* If the first opening be not sufficiently large, its dimensions may be increased to the necessary size, by means of a spear-pointed instrument. In introducing the trochar, care should be taken to prevent a too sudden entrance of the instrument into the cavity. Without this precaution, it might be suddenly forced against the opposite wall. The entrance is usually attended with a momentary severe pain, and the withdrawal of the instrument followed by a sudden gush of fetid mucus.

It is not always necessary to perforate the floor of the antrum after the extraction of the tooth; it occasionally happens, as has already been remarked, that some of the alveolar cavities communicate with it.

An opening having thus been effected, it should be prevented from closing, until a healthy action is established in the lining membrane, and for this purpose, a bougie, or leaden or silver canula, may be inserted into the opening and secured to one of the adjacent teeth. It should, however, be removed for the evacuation of the secretions, at least twice a day. The formation of an opening at the base or most dependent part of the sinus, will, in those cases where a fistula has been previously formed, in most instances, be followed by its speedy restoration. Having proceeded thus far, the cure will be aided by the employment of such general remedies as may be indicated by the

* In a collection of nearly one hundred jaws, presented to the Museum of the Baltimore Dental College, by Dr. Maynard, the floor of the antrum varies in thickness, from that of tissue paper, to half an inch.

state of the constitutional health, and for the dispersion of the local inflammation, leeches to the gums and cheek will be found serviceable. The antrum may, in the meantime, be injected with, at first, some mild or bland fluid, and afterwards with gently stimulating liquids. Diluted port wine, a weak solution of the sulphate of zinc and rose water, and also that of copper and rose water, have been recommended. Diluted tinct. of myrrh, may sometimes be advantageously employed, and when the membrane is ulcerated, a solution of nitrate of silver, will be highly serviceable. The author has used a solution of iodide of potassium with advantage; also, a weak alcoholic solution of tannic acid. For correcting the fetor of the secretions, a weak solution of the chloride of soda or lime, may be occasionally injected into the antrum.

In cases of muco-purulent secretions simply, a weak decoction of galls may be injected into the sinus with advantage.

Injections of a too stimulating nature are sometimes employed. This should be carefully guarded against, by making them at first weak, and afterwards increasing their strength as occasion may require; but if symptoms of a violent character are by this means produced, they should be combated by applying leeches to the gums and fomentations to the cheek.

Dependent as these affections in most instances are, upon local irritants, greater reliance is to be placed on their removal and giving vent to the acrid puriform fluids, than to any therapeutical effects exerted upon the cavity by injections. As adjuvants, they are serviceable, but a cure cannot be effected while the exciting cause remains unremoved.

The following cases may serve to illustrate the treatment usually pursued in cases of this kind.

CASE 1st. Mrs. T., a married lady, of about forty-five years of age, of a bilious temperament, applied to the author for advice, in 1853. She had suffered from neuralgic pains in her face and temples, at times, for nearly twenty years, and

as all of her teeth, especially of the upper jaw, were so much decayed as to preclude the possibility of restoration, he urged their immediate removal. She submitted to the operation, hoping it would relieve her from the pain, to which, to use her own words, she had "so long been a martyr," intending to have the lost organs replaced with an artificial set. She called again in a few months, partly for this purpose and partly to obtain relief from pain which she still experienced. But now it was not so much diffused as formerly. It was almost wholly confined to the left side of the face. On inquiry, it was ascertained that fetid matter was occasionally discharged from the nostril of the affected side. This led him to suspect that the antrum was diseased. An opening was accordingly made through the alveolar border, at the point originally occupied by the second molar. The withdrawal of the instrument was followed by the discharge of a small quantity of purulent matter. The antrum was now forcibly injected with water. This caused the discharge of more than two table-spoonfuls of hardened flocculi from the left nostril, which from long confinement, was insufferably offensive. The injection was repeated until the antrum was completely freed from this accumulation. A solution of sulphate of zinc, in the proportion of six grains to the ounce of water, was now substituted. The sinus was injected daily with this for a little more than a week, and without any other treatment a complete cure was effected.

The particulars of the following case are obtained from "Observations of Bordenave on the Diseases of the Maxillary Sinus,"* a paper embodying reports of forty highly interesting cases.

CASE 2d. "In 1756," says our author, "I was consulted by a lady whose right cheek was tumefied. About a month previous she had experienced acute pain under the orbit of the affected side; and she had felt a pulsation and heat in the interior of the sinus, and the maxillary bone was slightly

* Mem. de l'Acad. Royale de Chirurg., vol. xii, obs. 3, p. 10.

elevated. These signs determined me to propose the extraction of the third molar tooth,* and the perforation of the antrum through the alveolus. The operation was followed by a discharge of purulent matter, the sinus was afterwards injected, the maxilla gradually reduced itself, and a cure was effected in about two months."

Although injections were employed in the above case, it was no doubt, the giving vent to the matter contained in the antrum that the cure was attributable. As it regards the cause that gave rise to the affection in the first instance, not a single word is said. It may have resulted from inflammation, lighted up in the sockets of one or more teeth, and propagated from thence to the mucous membrane of this cavity, or from inflammation produced by some other cause, and consequent obliteration of the nasal opening.

The following brief statement is taken from the history of a case narrated by Fauchard.†

CASE 3d. The child of M. Galois, æt. twelve years, whose first right superior molar was decayed, had a tumor situated anteriorly upon the upper jaw of the same side, extending up to the orbit. M. Fauchard, supposing this tumor, which was about the size of a small egg, had been caused by the carious tooth in question, determined on its extraction as the only means of effecting a speedy and certain cure, and the result proved his opinion correct. The removal of the tooth was followed by a large quantity of yellow serous matter, which, on examination, was found to have escaped from the antrum. The tumor disappeared soon after the discharge of the matter, and a complete cure was effected.

Bordenave, in noticing the foregoing case, does not believe that the tumor communicated with the maxillary sinus, for the reason that the matter escaped through the alveolus of the first molar immediately after its extraction. He, however, admits that the acumen and knowledge of Fauchard,

* The bicuspid is called by most French writers, molars, and by the "third molar tooth," he means the one which we call the first.

† *Le Chirurgien Dentiste*, tom. i, obs. 8, p. 483.

are such as to have prevented deception in the case. Admitting, then, the statement to be correct, and surely the circumstance mentioned by Bordenave does not in the least tend to invalidate it, for it is of frequent occurrence, a cure is effected simply by the removal of a decayed tooth, to the irritation produced by which the disease was undeniably attributable. The two following cases are described at length by the last named author in the "*Memoirs de l'Academie Royale de Chirurgie.*"*

CASE 4th. A woman, in 1731, had the first superior molar, the crown of which had been destroyed by caries, extracted. Not many days after the operation, she was attacked with pain in the upper jaw, which extended from the maxillary fossa to the orbit. The pain was so great as to deprive her of rest, but there was no tumefaction of the cheek or gums. An opening through the alveolus into the sinus was discovered, into which a probe was introduced by a surgeon. The withdrawal of this was followed by a discharge of yellow fetid matter. M. Lamourier, who was afterwards consulted, removed from the opening a tooth that had been thrust into the antrum and prevented the egress of the matter, which, by its retention, had become purulent. Injections were employed, a part of which, at the expiration of thirty days, escaped from the nasal opening. A perfect cure was soon after effected.

In this case, the affection of the sinus, was evidently the result of the injury inflicted upon the socket of the first superior molar, in an attempt at the extraction of the tooth. Inflammation was excited by this and the presence of the tooth that had been thrust into the antrum, which extended itself to the lining membrane of this cavity, and caused a temporary obliteration of the nasal opening, so that to effect a cure it was necessary to obtain free vent for the retained matter. In restoring a healthy action to the mucous mem-

* Vide vol. xii, 12mo, Observations 5 and 6, pp. 12 and 19.

brane of the cavity, the injections may have been serviceable.

CASE 5th. A girl, æt. twenty-six years, in having a decayed and painful superior dens sapientiæ on the right side extracted, the tooth was broken and all the roots but one were left in their sockets. These caused an abscess to form, and this was followed, for a short time, by a subsidence of the pain, which, however, soon returned, and a dull, heavy sensation was felt in the antrum of the affected side. From thence the pain extended to the eye and ear. The gums at length became tumefied, and the pain less constant; the patient, although five teeth were in the meantime extracted, remained in this condition for five years. At this time, 1756, M. Beaupreau, who was consulted, found, on examination, that the gums where the first tooth had been extracted, had not entirely united, and a small tubercle had formed, from which a fluid of a bad smell and reddish color was discharging itself. He introduced a probe into the fistulous hole of the tubercle, which after having overcome some obstacle that at first impeded its passage, penetrated the antrum. The opening was enlarged and mercurial water applied to the carious bone, but it soon closed, and the pain which had ceased, returned. Injections were resorted to. These discharged themselves in part through the nasal opening, and the patient continued in this way until an exfoliation of the bone took place, when a cure was effected.

The cause of the disease in this, as in the preceding cases, was alveolo-dental irritation, and a cure would at once have been accomplished by the removal of the roots of the tooth that had been left in their sockets, as was proven by the fact that it was not until they were thrown off with their exfoliated alveoli, that it was effected.

In alluding to these and similar cases, Bordenave concludes there are not many cases where the extraction of teeth simply, will suffice to effect a cure. This inference, to say the least of it, is unfair, for in the case last given, it was to the presence of the roots of a tooth, that had been

fractured in an attempt to extract it, and left in their sockets, that the affection was attributable, and we have good reason to believe, that the cure was wholly owing to their removal.

The history of the following exceedingly interesting case, which was communicated to the Faculty of Medicine, by Professor Dubois, is contained in the eighth number of their bulletin for the year 1813, and also in Boyer's work on Surgical Diseases.

CASE 6th. Upon a child between seven and eight years old, at the base of the ascending apophysis of the superior maxillary bone, a small hard round tumor of the size of a walnut, was perceived by its parents. About a year after, the child fell upon its face, and caused a considerable discharge of matter from its nose, at the same time bruising the tumor. No other injury was produced, and the tumor did not increase perceptibly in size, from the eighth to the fifteenth year. During the next year, however, it sensibly augmented, and from the sixteenth to the eighteenth year, it attained so great a volume that the floor of the orbit was elevated, which caused a diminution in the size of the eye, and restricted the motions of the eyelids. The arch of the palate was depressed and the nasal fossa almost closed. The nose was forced to the right side of the upper part of the tumor, and there was a considerable elevation beneath the suborbital fossa. The skin below the inferior eyelid was of a violet red color, and very tense. The upper lip was elevated, and the gums on the left side protruded beyond those on the other side of the arch. Respiration was painful, and the patient spoke with difficulty. Sleep was laborious, and mastication was attended with pain. "In this state," says M. Boyer, "he was seen by M. Dubois, September 1st, 1802, but as he was not able to determine on the proper operation, M. Sabatier, M. Peletan and himself were called in. It was the opinion of all, that there was a fungous tumor of the antrum, and for the removal of this, M. Dubois was requested to make choice of his own method of operating.

A fluctuation was felt behind the upper lip, and this determined M. Dubois to commence the operation by making an incision there. This was followed by a discharge of a large quantity of a glairy lymphatic substance. Through this opening a sound was introduced into the antrum, and to M. Dubois' surprise, this cavity contained no tumor, but upon moving the sound about, it struck upon a hard substance, in the most elevated part of the sinus, which, on being removed, proved to be a canine tooth. Preparatory, however, to its extraction, two incisors and one molar were removed and their alveoli cut away. Injections were afterwards employed and the patient was soon restored to health.

It is not necessary to stop to inquire how this tooth got into the antrum; aberrations of this sort in the growth of the teeth are frequently met with, and some precisely similar instances have already been referred to.*

In all the cases which have as yet been noticed, the affection was traceable to local irritation, and in all, except the last, it had originated in the alveolar ridge. The following case of muco-purulent engorgement may be thought by some to have been occasioned by a different cause. Yet, there are circumstances connected with the history of even this case, that go to justify the belief, if the teeth had been in a healthy condition the affection would not have been produced.

Case 7th. Mr. G——, a laborer, æt. about thirty, of a decidedly scorbutic habit, applied in the spring of 1834, to an eminent medical gentleman of Baltimore, to obtain his advice concerning an affection of the left side of his face, under which he had been laboring for several months. The physician to whom he applied, after having examined the case, came to the conclusion, that it was mucous engorgement of the maxillary sinus, and requested him to call upon us, and have one of his molar teeth extracted, and the floor of the antrum through its alveolus pierced. He at the same

* Vide Mem. de l'Academie de Chirurg., vol. v, Mem. 257.

time desired, that if his opinion in regard to the nature of the disease proved to be correct, we should take charge of the case altogether. On examining his mouth, we discovered that nearly all the teeth of both jaws, the gums and alveoli were extensively diseased, and, on inquiry, obtained from him the following statement with regard to the commencement and progress of the affection.

About six months previous to this time, having been exposed, while pursuing his ordinary avocations, to very inclement and several sudden changes of weather, he contracted a severe cold ; in consequence of which, he was confined to his bed for several days ; during this time, he was twice bled, took two cathartics, and other medicines.

The disease at first concentrated itself in his head, face, and jaws, which, at the expiration of eight or ten days, was subdued by the above treatment, with the exception of the pain in his left cheek, and soreness in the upper teeth of the same side. The pain in his cheek, although not constant, still continued ; the nasal cavity of that side ceased to be supplied with its usual secretion, the teeth became more sensitive to the touch, and, finally, at the end of four months, a slight protuberance of the cheek was observable, accompanied by a tumor upon the left side of the palatine arch, which, when we first saw him, had attained to half the size of a black walnut, and it was by the fluctuation felt here, that the physician whom he first consulted, was induced to suspect the true nature of the disease.

Acting under the direction of the medical gentleman in whose care the patient had placed himself, we extracted the second left superior molar, and through its alveolus penetrated the antrum by means of a straight trocar, after the withdrawal of which, a large quantity of glairy, fetid mucous fluid was discharged. The perforation was kept open by means of a bougie, secured with a silk ligature to an adjoining tooth, as recommended by Deschamps, and the antrum injected three times a day. At first, simply with rose water, to which a small quantity of sulphate of zinc was af-

terwards added. By this treatment, the lining membrane of the antrum, at the expiration of five weeks, was restored to health, and the secretions that escaped through the perforation, no longer exhaled fetid odor.

The patient, not experiencing any inconvenience, withdrew the bougie, and allowed the aperture to close. In about two months, he again presented himself to the author similarly affected as when he first saw him. He now extracted the first superior left molar, and perforated the antrum through the alveolus, and a quantity of fetid mucous fluid was again discharged; the dens sapientiæ, and the first and second bicuspsids of the affected side, which were carious, were also extracted. Injections of sulphate of zinc and rose water, diluted tincture of myrrh, diluted port wine, and a decoction of nut galls, were alternately employed for three months, at the expiration of which time, the nasal opening, which had been previously closed, was re-established, and a perfect cure effected.

The condition of the teeth in the case just narrated, may not be thought to have exerted any agency in the production of the affection of the antrum, but there are circumstances connected with its progress that would seem to justify a different conclusion.

The presence of decayed teeth beneath the sinus, may not only have contributed to aggravate the morbid action lighted up by the cold which he had taken, but may also have caused it to locate itself in this cavity; and the fact that the inflammation of the lining membrane and the obliteration of the nasal opening continued until they were removed, would, at least, seem to warrant such an inference. That the injections were beneficial, we do not doubt, but that the cure was affected by them, no one, we think, will dare to affirm. We are far from believing that the presence of the decayed teeth was the sole cause of the disease of the antrum; that they contributed to, and protracted it, we cannot hesitate to believe, and but for the increased excitability, and, perhaps, actual inflammation, induced in the

mucous membrane, by the exposure of the patient to inclement and sudden transitions of weather, it is probable the sinus would never have become affected. We think it not unlikely that, notwithstanding the disturbance which may have been originated in it by this cause, no very serious or lasting morbid effect would have been produced, if the teeth and alveoli had been in a perfectly healthy condition.

The particulars of the following highly interesting case were communicated to the author by Dr. L. ROPER, dentist, of Philadelphia, in a conversation which he had with him in 1845.

CASE 8th. Miss M——, a young lady from the West Indies, of about fourteen years of age, had a fistulous opening beneath the right orbit, communicating with the maxillary sinus. By means of a probe introduced through the opening into this cavity, the apices of the roots of the first superior molar could be distinctly felt.

Medical aid was sought at an early stage of the disease, but as no permanent benefit resulted from the treatment adopted, the young lady, at the expiration of nine months, was brought by her father to Philadelphia, and in the spring of 1831, placed under the care of the late Dr. Physick, who, suspecting the affection of the antrum had resulted from, and was still kept up by, irritation, produced by the first superior molar of the affected side, which was considerably decayed, directed her to be taken to Dr. Roper, who, concurring with him in opinion, at once extracted the carious tooth. The operation was followed by the immediate discharge of a large quantity of thick, muddy, and greenish matter. The fistula under the orbit soon closed, and without further treatment, a perfect cure was accomplished in the course of a few weeks.

The foregoing are all the particulars which we could obtain concerning this interesting case. We have no doubt if all the circumstances connected with its early history were known, it would be found to have resulted from in-

flammation of the lining membrane of the antrum, caused by irritation in the socket of the tooth which was extracted. This opinion is sustained by the facts, that this tooth was affected with caries, and that its removal was followed by the immediate cure of the disease.

In Bordenave's collection of cases of diseases of the maxillary sinus, published in the Memoirs of the Royal Academy of Surgery, there are several examples similar to the one just narrated. We subjoin a description of the two following:

CASE 9th. A servant of the count of Maurepes had been afflicted for six months with a fistula upon the left cheek, a little below the orbit, which penetrated the maxillary sinus, caused by the spontaneous opening of an abscess. The third and fourth molars, (which are the first and second according as the teeth are now designated,) both of which were considerably decayed, were extracted by M. Hevin. As there were no openings through the alveoli, he perforated one with a trocar; this opening gave vent to a great quantity of putrid sanies, and did not close for more than a year after it was made. The fistula of the cheek healed in about ten days.

CASE 10th. In 1717, a soldier of the regiment of Bassigny, who had for a long time a fistula in his cheek penetrating into the maxillary sinus, was treated for it at the Hotel Dieu, of Montpellier. The matter settling near the orifice of the fistula, prevented it from closing. Mr. Lamourier, on examining the mouth of the soldier, perceived that the second superior molar was decayed; this he extracted and profited by the alveolar cavity, in opening the base of the sinus. The fistula of the cheek was by this means cured in a few days, but the counter opening was not immediately permitted to close.

In cases of fistula resulting simply from engorgement of the sinus, the treatment, as has been shown by the result of that in the foregoing cases, consist in the formation of a counter opening, which should always be affected at the most dependent part of the cavity, and in the removal

of all sources of local irritation. Injections should also be employed.

In the cases thus far presented, we have selected such as were not complicated with abscesses, ulceration of the lining membrane, or caries of the surrounding osseous walls; but to the existence of the two last, the affections, on which we have been treating, often give rise. We will not extend our remarks further upon mucous engorgement and purulent conditions of the secretions of this cavity. The next form of disease on which we propose to speak, is abscess—an affection, differing in all its characteristics from those thus far treated.

CHAPTER FOURTH.

ABSCESS OF THE MAXILLARY SINUS.

THE formation of abscess in any other part of the maxillary sinus than at the extremity of the root of a tooth which has penetrated the cavity, is exceedingly rare. There are but two well authenticated cases in which it has happened, so far as we have been able to ascertain, on record. One of these is described by Mr. Thomas Bell,* and the other by Bordenave.† The abscess in both instances was seated in the upper part of the antrum, beneath the orbit. But as we shall have occasion to refer to these cases again, it is not necessary to say more concerning them at this time.

Dr. Hullihen, in a well written article in the American Journal of Dental Science,‡ contends that abscess of the antrum, as well as alveolar, consists in the effusion of pus, formed in the pulp cavity of a tooth, between the bone and lining membrane." That this view of the subject is incorrect, is proven by the fact, that abscesses are almost as frequently formed in the sockets of dead teeth as living teeth. The matter from alveolar abscess, in those cases where the plate of bone intervening between the extremity of the root of a superior molar or bicuspid, is thinner than the surrounding osseous wall, often escapes through it into this cavity, after having first, as Dr. H. justly remarks, effused itself between the bone and lining membrane. In this case, it cannot properly be termed an abscess of the antrum. Although the matter escapes into this cavity, and, in con-

* Vide Anatomy, Physiology and Diseases of the Teeth.

† Vide Mem. de l'Acad. Royale de Chirurg., vol. 12, ed. 12mo, obs. xi, p. 31.

‡ Vide vol. ii, p. 179.

sequence, becomes involved in disease, yet the disease having originated in the alveolus of a tooth, which is still its principal seat, is, in the strictest sense of the term, alveolar abscess. It sometimes happens that pus from an abscess, formed in the socket of a superior molar, discharges itself into this cavity, and escapes through the opening into the nose. The pulp may suppurate, and the matter be confined in the cavity of the tooth for a long time, or be discharged through a decayed opening in the crown, communicating with the internal cavity, without causing alveolar abscess. The purulent matter contained in the sac at the extremity of the root of a tooth, is not always formed, as Dr. H. supposes, in the cavity of the tooth. The quantity of pus discharged from an alveolar abscess is oftentimes greater than that which could be formed by the suppuration of the soft tissues contained within the cavity of a tooth, and, besides, after this matter has been discharged, it cannot again be reproduced here, and, consequently, any matter which may afterwards accumulate in the cavity of the tooth, must be secreted by the soft parts about the extremity of the root. Again, abscesses often form at the extremities of the roots of teeth, after their internal cavities have been filled to their very apices. The alveolo-dental membrane at the apex of the root of a tooth, around the nerve cord, are more vascular, and endowed with greater nervous sensibility, than at any other part, consequently, the inflammatory action here is always the greatest, and it is here that suppuration first takes place.

The apices of the roots of the first and second superior molars, when they do not actually perforate the floor of the antrum, are often above its level, and covered by only a very thin shell or cap of bone, and hence, in case of abscess in one of these, although strictly alveolar, the matter is more liable to make for itself a passage into this cavity, than through the gum into the mouth. When this happens, it gives rise to inflammation of the lining membrane, causing its secretions to become more or less vitiated, and

often leads to an erroneous opinion concerning the true seat of the disease.

It is only when the root of a tooth actually penetrates the floor of the antrum, or the tubercle at its apex is actually situated in it, that the abscess can properly be said to be of this cavity. When the root does penetrate it, the tubercle, although formed at its apex around the nerve cord, as it is commonly called, is between the lining membrane and periosteal tissue, both of which, in the immediate vicinity, become directly involved in inflammation, and this sometimes extends to every part of the cavity, causing in some instances, obliteration of the nasal opening. This, however, does not often occur, but when it does, is followed by engorgement of the sinus, occasionally, by ulceration of the lining membrane and disease in the surrounding parts.

It is sometimes the case, that the plate of bone intervening between the extremity of the root of a tooth, around which a tubercle has formed, and the antrum, is destroyed, and the tubercle, instead of being wholly confined within the alveolus, is forced up, as it enlarges, almost entirely into this cavity. The inflammation, after having attained a certain height, is succeeded by suppuration, and the secretion of pus goes on until the sac bursts, when the matter is discharged, and, mixing with the mucous secretions of this cavity, ultimately escapes with them through the natural opening into the nose.

As it regards the morbid effects produced upon the lining membrane and surrounding bony parietes of the antrum, by an abscess of this kind, it is of little consequence whether it be formed in it, if the matter be discharged there, or in the alveolus of the tooth that gave rise to it. The effects are nearly the same in one case as in the other. If the general health of the patient be good, and the natural opening of the sinus remain pervious, they seldom assume an alarming character; under other and less favorable circumstances, the most dangerous and aggravated forms of disease may result from abscess in either place.

SYMPTOMS.

In the incipient or forming stages of abscess of the maxillary sinus, the symptoms are similar to those that characterize inflammation of the lining membrane, or violent inflammatory tooth-ache. The pain is generally most severe in the upper part of the alveolar ridge, above one of the molar or bicuspid teeth. From thence, it often extends to the lower part of the orbit, ear, temple, muscles of the cheek and scalp. It is more or less constant, and a throbbing sensation is felt high up in the alveolar border beneath the cheek. If the abscess is seated at the apex of the root of a tooth, this organ will appear slightly elongated and sore to the touch; the cheek, in most instances, is slightly tumefied, and more or less flushed.

The pain, after having continued for several days, is succeeded by suppuration, when it immediately subsides. Slight paroxysms of cold and heat are now felt, and if the natural opening of the antrum is not closed, purulent matter will, occasionally, be discharged.

If the abscess is seated in any other part than the base of the antrum, the symptoms may differ in some respects from the foregoing. If purulent matter, or mucus mixed with pus, be discharged from the nostril of the affected side, when the patient inclines his head to the opposite, or makes a sudden and forcible expiration through it, while the other is closed, the existence of abscess in this cavity will be very conclusively indicated.

The abscess having burst, pus will be discharged from time to time, for several days, which will escape through the nasal opening, with hardened flocculi or other foreign matter, and then it will cease altogether or very nearly. The disease, however, if the irritant which gave rise to it still remains, is by no means cured. A recurrence of it is liable to take place every time the patient takes cold, when all the symptoms just described will be again experienced, and each

succeeding attack leaves the parts implicated in the disease in a more unhealthy condition, and, as a consequence, more susceptible of being acted upon by morbid irritants. Suppuration, also, at each successive attack, takes place, and the pus gradually assumes a more unhealthy character.

C A U S E S .

It will not be necessary to say much concerning the causes of abscess of the antrum. It is sufficient to state, they are the same as those of tooth-ache, namely, inflammation of the alveolo-dental periosteum or inflammation of the lining membrane of this cavity. It is to the presence of one or other, or both of these that it is attributable. These may be occasioned by caries of the teeth, or a dead or loose tooth, or a blow upon the cheek, or by exposure to sudden changes of weather. Other causes may sometimes be concerned, but the foregoing are the principal, and all it is necessary to enumerate.

T R E A T M E N T .

In the cure of abscess of the maxillary sinus, as well as that of a muco-purulent condition of its secretions or engorgement, the first and most important indication to be fulfilled is to obtain vent for the matter from the inferior part of the cavity. The best method of doing this has been described, and it is unnecessary to recapitulate the directions already given for the accomplishment of this object.

The formation of abscess might, however, in almost every instance be prevented by the timely adoption of proper treatment. On the occurrence of severe, deep-seated and throbbing pain in the upper part of the alveolar ridge, or just above it in the region of the antrum, such as has been described as attending the formation of abscess in this cavity, or that of the alveolus of a superior molar; or if the

tooth directly beneath the place where it was first felt, be considerably decayed, or its lining membrane exposed; or if it be dead, loose, or the socket much diseased, it should be immediately extracted. By this simple operation, the formation of abscess not only in the socket, but also in the antrum, may, in almost every instance, be prevented.

The curative indications, if the abscess is of recent formation, and has resulted from the presence of a diseased tooth, are similar to the preventive. The first thing to be done is to remove the tooth that caused it, and if this operation is not delayed too long, it, in most instances, will be all that is necessary to effect a cure. In addition to this, Dr. Hüllihen recommends the perforation of the antrum;* but in those cases where the abscess has formed at the apex of the root of a molar, this is not necessary; because in all such cases, the alveolus communicates with this cavity, so that on the removal of the tooth, there will be a sufficiently large opening communicating with it; besides, the tubercle or sac, although situated within the sinus, is usually brought away with the tooth.

When the abscess has been of long standing, and the lining membrane of the antrum has become seriously affected, in addition to the removal of the tooth, other treatment will have to be resorted to. The opening into the antrum, if necessary, should be enlarged, and it should be prevented from closing until the health of the lining membrane is restored. For the promotion of this, injections, such as have been already recommended, will be found serviceable.

In cases of simple abscess of the antrum, seated at the apex of the root of a superior molar, we have never found it necessary to adopt any other treatment than the foregoing. It may, however, in some instances, be necessary to remove more than one tooth.

We might, if it were necessary, give the history of several interesting cases of abscess of this cavity, which had

† American Journal of Dental Science, vol. ii, p. 182.

originated at the extremity of the roots of teeth, but as the treatment is so simple, it would be enlarging this portion of our work to no purpose to do so.

But before we conclude our remarks upon abscess of this cavity, we will give the history of one case to which allusion has before been made. The following detailed statement we quote from Mr. Bell's treatise on the teeth.

CASE 11th. "Mary B——, aged eighteen, of an unhealthy and somewhat strumous aspect, of languid disposition, and of retiring and timid habits, came under my care on the 3d of January, 1817, in consequence of a severe and continued pain on the left side of the face, of a dull heavy character, and apparently deep-seated; but occasionally darting in acute paroxysms across the face towards the nose. The cheek was swollen, and the palate somewhat enlarged. About a year before, the first superior molar of that side had been extracted on account of severe pain in the face, but without producing any relief, and the pain was consequently attributed to rheumatism, from which complaint she had long suffered to a great degree, in the shoulder, hip, and other joints, and for which she had been under the care of many medical practitioners, both in London and Bath, having been sent to the latter place for the use of the waters. When I first saw her, the general health was much deranged: the stomach, bowels and liver performed their functions very imperfectly; and the uterus partook of the general sluggishness of the system, menstruation being almost wholly suppressed, and the periods only indicated by increased indisposition, and especially by an exacerbation of the pain in the face.

"No discharge had taken place from the nose, but from the nature and situation of the pain, the direction of its paroxysms, the enlargement of the cheek and palate, and from an occasional trifling discharge of pus from the alveolus of the tooth which had been extracted, I could not doubt that the antrum was the seat of the disease. On examining the teeth, I found that the second bicuspid was also

diseased, and as it had at times occasioned considerable pain, I extracted it with the view of removing every possible source of irritation.

“Six leeches were ordered to be applied to the face, and afterwards the continued application of a cold lotion. Medicines were also administered with reference to the general health, both as regarded the digestive and uterine functions; and on January 7th I determined on puncturing the antrum. I consequently introduced the trochar through the anterior alveolar cavity of the first molar, and found that when the instrument came in contact with the lining membrane, the most acute pain was produced, indicating the existence of a high degree of inflammation in that structure. On withdrawing the trochar, when the antrum was freely opened, I was surprised, and a little disappointed at finding that not the smallest discharge made its appearance. There was a small quantity of glairy mucus, but nothing more. I introduced the blunt end of a probe, and found that the opening was quite free; but on passing it upwards towards the orbit, its passage was resisted by a firm elastic substance, which gave the impression that a solid tumor existed in the upper part of this cavity, and which produced intolerable pain on being pressed with the probe. I now injected some tepid water, and found that the nasal opening was pervious, as the water passed freely into the nose. As the operation had produced a considerable increase of pain, and as the parts appeared a good deal inflamed, I ordered six leeches to be applied, the bowels to be freely opened, and an opiate to be taken at night.

“January 9th. The pain had been extremely severe ever since the operation, with scarcely any mitigation, excepting for a few hours after the application of the leeches. A probe now introduced into the antrum, met with similar resistance, but much nearer the orifice than before, proving that the tumor had increased; and on injecting warm water, it no longer passed into the nose. The leeches, the aperient, and the opiate were repeated.

“January 11th. The pain has continued without cessation, and no sleep has been produced by the opium. The inflammation is not, apparently, reduced. Pulse one hundred, small and feeble. The palate is a little enlarged, but not more so than might be accounted for, by the thickening of the integuments by inflammation. I could now distinctly feel with a probe, that the tumor was not only increased in size, but that it had become softer, yielding in some measure to pressure, and conveying the impression that it contained fluid. I therefore introduced a sharp pointed instrument, which with a little force, pierced the tumor, and a gush of pus instantly took place, with immediate relief to the symptoms.

“Here, then, was the sac containing pus, existing doubtless as a distinct cyst, the result of inflammation in the membrane; for it is scarcely probable that the membrane itself had become separated from its attachment by the formation of pus between it and the bone. That the former was the true situation of the disease, may be inferred from the fact that no subsequent caries of the bone took place, which would, undoubtedly, have been the case, had the matter been formed in contact with the bone; and it could scarcely have been produced between the mucous membrane and the periosteum, as these two structures, though essentially distinct from each other, are inseparably connected.

“The pus continued to be discharged for a day or two, and then entirely ceased. In passing the probe a week after the former operation, I found the same resistance as before, and in the same situation; the cyst was again punctured, and again the pus was discharged. This alteration of the repletion and evacuation of the cyst regularly recurred for a considerable time, but the opening into the nose did not again become stopped. The general health, however, in the meanwhile, improved, and the pain in the face was greatly diminished, returning only, with any degree of violence, when the cyst was full.

“At length the repeated perforation of the sac, followed

by the use of strong astringent injections, and aided by the remedies that were directed to the state of the general health, restored the antrum to a healthy condition ; the menstrual disturbance was by degrees entirely obviated, and the stomach at the same time assumed its healthy function ; but it was two years from the time when I first saw her before she had recovered her health, which at the best was never robust."

There is a case described by Bordenave, which, in many respects, is similar to the foregoing, but having adopted a different treatment, the cure was more tardy. It was ultimately, however, effected. For the particulars of the case, the reader is referred to a Dissertation of the author on the diseases of this cavity, page 86.

Finally, that abscess does occasionally form in other parts of the antrum than the base, is conclusively proven by the cases described by Bell and Bordenave. It is true, these are the only ones of which we have any account, nevertheless, they establish the fact that it is possible for them to occur in any part of this cavity.

CHAPTER FIFTH.

ULCERATION OF THE LINING MEMBRANE OF THE MAXILLARY SINUS.

THIS is not an idiopathic affection. It is always, we believe, symptomatic of some other morbid condition of the mucous membrane of this cavity, and often gives rise to some of the worst and most aggravated forms of disease, to which it is liable. It is not a simple disease, but is complicated with the one that caused it, and often with some other to which it has given rise. We shall treat of it, however, as a separate affection. Its attacks are preceded by a purulent condition of the fluids of the antrum, and are often followed by fungi, and sometimes by caries of the surrounding osseous walls. The membrane covering the floor of the cavity, is usually first attacked; ulcers having formed here, they soon extend to other parts of the sinus.

Ulcers of this cavity present as great a variety of character as do those of other parts of the body. Their nature is determined by the state of the constitutional health and the causes that produce them. It is not necessary to go into a minute description of the various kinds of ulcers that occur in this cavity. It will be sufficient to state that the following varieties have been met with: namely, the simple, or those resulting from mechanical injury; the fungous, scorbutic, venereal, cancerous, gangrenous, scrofulous, inveterate, carious, &c.

In the simpler species of ulcer, the matter is of a thick consistence and nearly white, but as the disease increases in malignancy, it becomes thinner and varies in appearance from transparent to a dirty brown, yellow or black.

SYMPTOMS.

Many of the symptoms attendant upon ulceration of the mucous membrane of the maxillary sinus, are similar to some that accompany other affections of this cavity ; as, for example, deep-seated heavy pain in the cheek ; occasional escape of matter into the nose, &c. In addition to constant pain in the region of the antrum, the following symptoms may be enumerated. The escape of fetid sanies into the nose on the patient's inclining his head to the opposite side, or through an opening which it has itself effected, or that has been formed by art for its escape. Also the traversing of the ulcer from the interior through the bony walls of the cavity and external soft parts. An opening of this sort may be effected through the cheek, near, or even into, the orbit, which last has often happened ; at other times, it is effected through the canine fossa or palatine arch. Moreover, the matter escaping from the sinus, often has flocculi mixed with it, which is never the case in simple muco-purulent secretion of the sinus. These flocculi sometimes choke up the natural opening of the cavity and cause its secretions, together with those of the ulcers, to accumulate, and distend its osseous walls until they ultimately give way, or an opening is formed for their escape. It occasionally happens that the flocculi lodged in the nasal opening, suddenly give way, and permit the matter to pass into the nose.

When the ulcer is of a fungous character, the matter secreted is thin, of a dark brown or blackish color, and has mixed with it blood and pus.* It is, says Deschamps, slightly painful, and can only be distinguished from other ulcers by the introduction of the bougie into the sinus ; and like polypus, it is capable of spreading and penetrating every opening that will give it passage ; but, in consequence

* *Maladies des Fosses Nazales*, sec. 2, art. vi, p. 263.

of its being of a softer consistence, it makes less impression upon the surrounding parts.

If the ulcer be of a cancerous nature, the pain will be sharp and lancinating, affecting the whole of the side of the face; the matter will be serous, very fetid, and streaked with blood. If discharged through the natural opening into the nose, it will cause the pituitary membrane of the nasal cavity of the affected side to become exceedingly irritable, sensitive to the touch, and to ulcerate. The bones of the affected side of the face soon become softened or carious, the teeth loosen, the external soft parts inflame and ultimately ulcerate; openings are formed into the sinus, fever of a low grade supervenes, and ultimate death closes the scene.

C A U S E S .

A degenerated or altered state of the secretions of this cavity, is said to be the most common cause of ulcers in it.* This may be an exciting cause, and it may be one of the most frequent exciting causes, but were it not favored by constitutional predisposition, it would seldom give rise to them. Local irritation, whether produced by an altered condition of its secretions, or by the presence of decayed or dead teeth, the roots of teeth, or a blow upon the cheek, may be, and doubtless is, the exciting cause of ulcers in the mucous membrane of this cavity. This, however, in a subject of good constitutional health, would have to be very severe and continue for a long time, to occasion ulceration, and even then, a cure would soon be effected by the restorative powers of the economy. It is only in bad habits or debilitated constitutions, that malignant ulcers are met with in the maxillary sinus.

Deschamps, although he acknowledges that diseased teeth often exercise a morbid influence upon this cavity, and that the apices of the roots of these organs are sometimes in con-

* *Maladies des Fosses Nazales*, see. 2, art. vi, p. 159.

tact with its mucous or lining membrane, seems nevertheless to doubt that they have any agency in the production of ulcers. His reasoning upon the subject is far from satisfactory. While he admits that by the contact and adhesion of the dental periosteum and mucous membrane of the antrum, and the penetration of its floor by the roots of teeth, inflammation and ulceration may be produced, he denies that it can be positively proven. Although we may not be able to adduce positive evidence, the circumstantial proofs which we have, are so clear and strong, that no candid inquirer can, for a single moment, doubt that the disease in question, when favored by a bad habit of body, often results from dental or alveolar irritation. In reply to the question which he a little further on propounds, "How can the extraction of a tooth be of service in the subduction of inflammation of the mucous membrane with which the dental periosteum is only simply in contact?"* we answer, by this operation, a constant source of irritation may be, and often is, removed. Ulcers having absolutely formed, a cure cannot always be effected by the removal simply of the exciting cause.

T R E A T M E N T .

As in the case of mucous engorgement, the first indication of cure is to give egress to the purulent matter, and in this, as in the other affections, the opening should be formed at the most dependent part of the sinus; and this should be effected in the manner as before described, through the alveolar border, or rather alveolus of a molar tooth. It should be made large enough to admit the little finger, and if there be any teeth so much affected as to be productive of irritation to the parts subjacent to the antrum, they should be removed.

Free egress for the matter having been obtained, and all local irritants removed, the antrum should be injected from

* *Maladies des Fosses Nazales*, sec. 2, art. vi, p. 259.

time to time, with gently stimulating and detersive fluids. This, in cases of simple ulcer, if the constitutional health is not seriously impaired, will often be all that is required to effect a cure.

If the ulcer is of a fungous nature, the employment of escharotics, and sometimes even the actual cautery becomes necessary ; this last should be repeated until the fungi are completely destroyed. With regard, however, to the employment of escharotics, such as the nitrate of silver, sulphate of copper, etc., for the purpose of destroying luxuriant granulations in ulcers, Sir E. Home is of the opinion it is better to combine them with some other substance, so as to prevent them from immediately destroying the granulations. He believes when this is done, the surface of the ulcer, underneath, is more liable to reproduce them, than when they are removed by absorption, and it is for this reason he prefers, in the employment of caustics, to mix them with other substances, so that they shall only exercise a strong stimulating effect, and thus cause the granulations to be gradually removed by the action of the absorbents.

The surface of the ulcer should, if practicable, be kept clean by means of dossils of dry lint or pledgets spread with some simple ointment. The treatment of ulcers of this cavity, is usually attended with more difficulty, on account of their concealed situation, than those of most other parts of the body. Among other things, Deschamps recommends injections of a decoction of quinine. In many cases a lotion of sulphate of zinc may be used with advantage. The remedies to be employed in the treatment of ulcers of the maxillary sinus, as in the treatment of ulcers of other parts, should be varied to suit the indications of each particular case. In debilitated subjects, tonics, as quinine and preparations of steel, are often serviceable. There are some cases in which mercurials are beneficial. Strict attention should always be paid to the regimen of the patient, and such general treatment adopted as may be best calculated to restore

the constitutional health, for upon this, the cure of the local affection often depends.

If the ulcer is of an irritable nature, warm fomentations, (conveyed to the interior of the antrum by means of a properly constructed funnel,) of a decoction of poppy heads, chamomile flowers, or the leaves of hemlock, will often prove beneficial in soothing the pain. Tincture of myrrh, diluted, or a decoction of walnut leaves may be advantageously employed as injections in cases of indolent ulcers—the last of which is recommended as an application to ulcers of this character, in other parts of the body, by Hunezawsky, and both of which are favorably spoken of by Sir E. Home. This last named writer recommends “diluted sulphuric acid and the juice of the powder of different species of pepper in a recent state;” also nitrous acid diluted with water. The unguentum hydrargyri nitrate, mixed with lard, the ceratum resinae, and the unguentum elemi, mixed with the balsam of turpentine, are also recommended. The application of ointment to ulcers of this cavity can rarely be made.

Many of the ulcers of the maxillary sinus are regarded as incurable, as for example, such as are of a cancerous nature and ulcerated fungous hematodes. Although the resources of surgery have hitherto, in most instances, proved inadequate to the cure of these formidable diseases, nevertheless, they should be put in requisition, and we should endeavor to combat them by every means in our power. Deschamps says, the interior of the antrum should be exposed at the commencement of the disease. He recommends the formation of a large opening, if the alveolar ridge be healthy, above it, if not, through it, exposing as much of the cavity as possible. This done, he directs, if there is a cancerous tumor, that it be as thoroughly extirpated, by means of a curved and flat bistoury or curved scissors, as possible. All that may have escaped removal by this means, he says, should be touched with the actual cautery. These are the only remedies to be employed when the membrane is in a state of cancerous ulceration. The surgeon should

destroy the parts in such a way as to leave only the osseous surfaces, and he should pay some attention to these bony parts, which, also, he should carefully cauterize. The disease having been thus removed, the surrounding osseous walls which have been cauterized will soon exfoliate, when a chance for a cure will be afforded, and of which, if the neighboring parts have not been too extensively invaded, nature will avail herself. The administration of soothing and anodyne medicines are also directed. Arsenic has been employed with advantage as an external remedy in ulcers of this kind.

The following case of fungous ulcer, complicated with alteration of the walls of the sinus, is taken from Bordenave's collection of observations on the diseases of this cavity, in the *Memoirs of the Royal Academy of Surgery*. Although the history of the case, in its translation, is somewhat abridged, yet no important fact connected with it is omitted.

CASE 12th. The subject of this case was a woman twenty-six years of age; who having exposed herself, while in a critical state of health, to cold air, was, in 1759, attacked with acute pains in the left side of her upper jaw; in the alveolar ridge of which were the roots of several decayed teeth. The following day her jaw was swollen, and although the pain ceased in a few days, the swelling continued, without any change in the appearance of the skin; nevertheless, her face was deformed in shape. The orbitary apophysis of the maxillary bone became elevated, and the substance of the bone softened. The interior of the nose was affected and the opening of the sinus into this cavity was closed. The matter collected in the antrum began to escape, twenty-two days after the attack, through the alveoli.

In January, 1761, the symptoms becoming more aggravated, she went to Paris for medical aid. M. Beaupreau was consulted, and on examining the affected parts, determined on the extraction of the decayed teeth, which were considerably broken. They, however, adhered so firmly to

the alveolar cavities that he could not move them without shaking their sockets. This deterred him from proceeding with the operation as he had begun, and he resolved to remove the whole of the alveolar border with a bistoury, from the lateral incisor to the first molar, and in this way remove the teeth with the bone. This done, he made a section of the bone, which had become softened, with a pair of scissors, in the direction of the cuspidatus. The antrum was much dilated: its membrane fungous and ulcerated. He then treated it with detersive injections, adhesive dossils, covered with digestives, composed of the oil of turpentine. In addition to these, mercurial ointment and red precipitate were used. Alterative pills, and beverages clarified with cress, were also prescribed; this treatment was successful, for, five days after it had been commenced, the tumor had perceptibly diminished, the pus became of a better quality and less in quantity. At the expiration of two months, the discharge became mucous. Injections of lime water, at first strong, and afterwards milder, were used. The natural opening was closed, and continuing impervious, an opening through the base of the sinus was preserved. At the expiration of two months, the parts had recovered, and the general health of the patient was restored.

The medical treatment in the foregoing case was very proper; it accorded with the curative indications of the disease, but the surgical evidently involved a greater sacrifice of substance than was absolutely called for. The extraction of teeth was not, however, as well understood at that time as at present, and it was to the want of proper knowledge and skill in this department of surgery, that the removal of so considerable a portion of the alveolar ridge was had recourse to. It is often necessary to make a very large opening into the sinus, but it is seldom requisite to make one as large as that made in this instance; although nearly the same treatment was adopted in a case of a somewhat similar nature by Bourdet, the practice is nevertheless objectionable. When the subjacent bone and alveolar border are in a carious or

necrosed state, their removal would be proper, and there are diseases that occur in this cavity which render the operation necessary, but in neither of the cases just noticed, were the bones so carious, nor was the nature of the disease such as to require so large an opening. In the first case, the outer wall of the sinus, as would seem from the description given, was softened, but in the other, Bourdet says the bones were not diseased.

It sometimes happens when the opening through the alveolar border is very large, it never closes, and when the natural opening becomes obliterated, it is requisite to preserve an artificial one; in either of these cases the employment of an obturator is necessary to prevent particles of food and extraneous matter from getting into the sinus. Of these we shall hereafter speak.

The history of many highly interesting cases of ulceration of the mucous membrane of this cavity, might be introduced, but as this form of diseased action is so often complicated with caries, necrosis, and other alterations of its osseous walls, we have thought it would be as well to reserve them until we treat of those affections; which we shall now proceed to do.

C H A P T E R S I X T H .

CARIES, NECROSIS AND SOFTENING OF THE BONY PARIETES OF THE MAXILLARY SINUS.

THE osseous walls of the antrum, and sometimes the whole of the subjacent alveolar border, and that of the superior maxillary, the nasal, palatine and orbital bones, as well as some that belong to the base of the cranium and the malar bone, are involved in caries or necrosis. Mollities ossium, though rarely occurring in the alveolar ridge, frequently affects the walls of the sinus. Caries may affect a considerable portion of both for a long time, without completely destroying the vitality of the diseased parts. During its continuance fetid sanies is discharged from one or more fistulous openings through some part of the cheek, alveoli, gums, palatine arch, or into the sinus, and from thence through the natural opening into the nose. The disease eventually terminates in the decomposition and death of the parts affected, and then by an operation of the economy, they are separated from the living bone and thrown off, or in other words, exfoliated. Although caries ultimately causes the death of the bone affected by it, it does not always precede the destruction of vitality. The occurrence of necrosis, therefore, although it may result as a consequence of caries, is not necessarily dependent upon it.

When the parietes of the antrum or alveoli are affected by necrosis, the soft parts in contact with the diseased or dead bone, inflame, ulcerate and discharge fetid ichorous matter. The gums sometimes become gangrenous and slough. The destruction of the vitality of the osseous parts

often progresses very slowly, and thus, piece after piece, is exfoliated, until the disease is arrested.

Besides these affections, it not unfrequently happens that the osseous parietes of this cavity are so softened as to be easily bent. This alteration of the bone, as well as the others just noticed, are, in nearly every instance, preceded by some other form of disease.

The annoyance occasioned by caries and necrosis of the bony walls of this cavity or of the alveoli, to the unhappy patient, is very great. The fœtor of the sanies is sometimes almost insufferable; the matter often excoriates and inflames the parts with which it comes in contact to such a degree, as to cause them to become exceedingly sensitive and not unfrequently to ulcerate.

SYMPTOMS.

It is sometimes difficult to distinguish caries and necrosis of the bony parietes of the antrum from some of the other diseases of this cavity. They, therefore, often exist for a long time without being suspected. The signs that indicate mollities ossium, or softening of the walls, are such as not to be easily mistaken for those of any other affection. In this disease, the walls of the sinus yield to pressure, and regain their former shape when the pressure is removed. Its existence, therefore, may always be known by these signs, and as these are sufficient, it is not necessary to enumerate any others by which it is characterized. Caries and necrosis not being so easily detected, often make considerable progress before their existence is ascertained. The fœtor and appearance of the matter discharged do not always furnish a diagnosis that can be relied upon, inasmuch as some of the diseases that occur here cause its secretions to become equally as offensive as the sanies resulting from caries or necrosis, and not unlike it in appearance. Their existence may in most instances be inferred, from the discharge of dark-

colored fetid sanies. The exfoliation of pieces of bone will set all doubt at rest.

Caries or necrosis may often be detected by perforating the antrum and exposing the denuded or diseased bone; or when there is an external opening, by probing it. In this way any loose or dead bone may be felt with the instrument; and the diagnosis in either case will be satisfactory.

When caries or necrosis is situated in the alveolar border, or floor of the antrum, its existence can be more readily ascertained. The occurrence of either in the alveolar ridge, causes the gums to inflame; to assume a dark purple or livid appearance; to separate from the sockets of the teeth, and frequently to slough in large pieces and expose the caried or necrosed bone. When situated in the floor of the antrum, the rough denuded bone may be easily felt with a probe or stilet, introduced through the fistula in the gums or the alveolus from which the matter is discharged.

The pain accompanying these affections does not constitute a diagnosis of much importance, since this does not belong to the osseous tissue, but to the soft parts that cover it.

C A U S E S .

The immediate cause of caries and necrosis of the osseous walls of the antrum maxillare is suppurative inflammation, or the destruction of their periosteum; which may result from a purulent condition of the secretions of the mucous membrane, engorgement, tumors, a blow upon the cheek or from other kinds of mechanical violence. They may also arise from the irritation produced by diseased teeth.* The pressure of incarcerated fluids, may, perhaps, be regarded as the most frequent cause; and from this, too, results some

* Fouchard says, he saw, in the Anatomical Museum of the University of Copenhagen, caries of the bones of the face, produced by a molar tooth, the crown of which, having turned outwards, had penetrated the maxillary sinus. *Mem. de l'Academie de Chirurg.*, vol. v, mem. 257.

of the most aggravated forms of disease that ever attack this cavity.

A morbid action kept up in the periosteum for a long time, by ulceration of the lining membrane, or any other aggravated form of disease in the sinus, or neighboring soft parts, is apt to give rise to caries of the bone, but when the inflammation is so severe as to cause the immediate destruction of the periosteal tissue, necrosis at once takes place.

The softening of the bone, seems to be the result of the action of some solvent fluid upon it, capable of decomposing or breaking down its calcareous molecules. Although inflammation and ulceration are always present, and appear necessary to the exudation of this fluid, its production, nevertheless, seems to be dependent upon some peculiar state or habit of body.

T R E A T M E N T .

Complicated, as are most frequently, caries, necrosis and other alterations of the osseous walls of the maxillary sinus, with other affections of this cavity, their cure is often difficult and generally tedious. The first indication to be fulfilled, however, in their treatment, as in the case of engorgement, and of a muco-purulent condition of the secretions, is to obtain free egress for any fluids which may have accumulated here. This may be effected in the manner as before described. In addition to this, if the disease of the osseous tissue is complicated with any other affection of the sinus, such means as are necessary for the cure of the disease with which it is complicated, should at once be employed. It is not necessary here to describe the treatment of the other diseases of this cavity, as that has already or will hereafter be done.

Deschamps, in treating upon these affections, recommends the employment of detersive and stimulating injec-

tions, a decoction of quinine, tinct. of myrrh and aloes, &c. These last, he says, may be introduced as injections, or by means of pledgets moistened in them. He also directs the cavity to be "cleared of all foreign matter which may have obtained admission into it." This treatment, having a tendency to promote a healthy action in the lining membrane, will often be all that is required. It should be continued until the caried or necrosed bone has exfoliated, and the secretions of the antrum cease to exhale an offensive odor. The dead bone, however, having exfoliated, a cure is generally soon effected.

It sometimes happens that the disease of the bone has been produced by some very malignant and incurable affection of the soft parts. In this case, the resources of art will, of course, prove unavailing. When the disease of the bone has extended itself to the greater part of the superior maxillary and the bones with which it is connected, as, for example, the nasal, palatine, orbital, &c., the most that can be hoped for, from the skill of the physician, is a palliation of the symptoms. Art, in such cases, can seldom effect a cure. There are other cases in which it can only retard the progress of the disease, or assist nature in her efforts to separate the dead from the living bone.

It is impossible to lay down rules for the treatment of alterations of the walls of the maxillary sinus, from which it will not be necessary occasionally to deviate. It will be sufficient to state, that in those cases, where they are extensively involved in caries or necrosis, it will be proper, in addition to perforating the base of the sinus, if by this means the dead bone cannot be so exposed as to enable the surgeon to detach it from the living, to cut away the whole of the alveolar border beneath the cavity, or to penetrate the sinus above it, or even, as Deschamps recommends, "through the cheek itself, whether there be an ulcer penetrating these parts or not." Having, by this means, exposed the necrosed bone, it should be carefully detached from the sound and removed.

The character which the affections of this cavity put on, being determined by the state of the constitutional health, or some particular vice of body, it often becomes necessary in their treatment, to have recourse to general remedies. If the subject is of a scrofulous or scorbutic habit, or is affected with any specific constitutional vice, such remedies as are indicated by the affection of the general system should be employed.

Although the character and malignancy of the disease are determined by the state of the constitutional health, or disposition of body, its occurrence seems to be dependent upon local irritation. Its continuance, in many instances, results from this; and the cure, in cases of this kind, soon follows the removal of the cause that gave rise to it. In a case, the history of which we are now about to detail, an example of this sort is furnished.

CASE 13th. L. S——, a maiden lady of about thirty years of age, of a scorbutic habit, had been affected with pain in her left cheek and alveolar ridge for nearly two years; which at times had been almost insupportable. Nearly all her teeth were affected with caries, and from between the necks of several, on the left side in the superior maxillary and gums, fetid sanies had been exuding for two or three months. Her appetite had become greatly impaired, and a tumor half the size of a black walnut, having formed upon the palatine arch of the affected side, she became alarmed, and in the fall of 1840, came from her residence on the Eastern Shore of Maryland, to Baltimore, in pursuit of medical aid. She applied to Professor T. E. Bond, who, after investigating the case, and satisfying himself that the affection was the result of the diseased condition of her teeth, advised her to place herself under our care, which she did on the following day.

The sockets of four of the teeth of the affected side, in the superior maxillary, were, on examination, found to be in a necrosed condition, as was also a part of the palatine bone of the same side. The gums around these teeth had sepa-

rated from the alveolar processes, and had a dark livid appearance. A thin dark colored, ichorous matter, which, when brought in contact with silver, almost instantly turned it black, was constantly exuding from between them and the necks of the teeth. The left nostril was dry, and the opening from the sinus had evidently closed. Exceedingly fetid matter had been discharged from it during the early stages of the disease. The tumor on the left side of the arch of the palate was soft and elastic. When pressed, dark colored sanies was discharged from the alveoli, and it then, for a time, disappeared.

The alveolar processes being in a necrosed and loose condition, it was with some difficulty we succeeded in removing the bicuspsids, and the first and second superior molars of the left side, without bringing their sockets with them. The operation was followed by a discharge of a considerable quantity of fetid sanies; and, in a few days, the alveoli having become completely detached from the sound bone, we removed them, together with a part of the floor of the antrum. The opening thus formed into the sinus was large enough to admit the end of the fore-finger. Several small pieces of bone were afterwards exfoliated, from where the teeth had been extracted, and three pieces from the left side of the palatine arch.

Without any other treatment, the place from which the teeth and alveoli had been removed, except the opening that communicated with the maxillary sinus, had in about seven weeks, become entirely covered with firm and healthy granulations. From the opening into the antrum, fetid matter was still discharged. This became less and less offensive, until at the expiration of six or eight weeks, the opening into the nose having become re-established, it lost its fetid odor, and the aperture at the base of the sinus soon after closed.

Thus, in a little more than three months, a complete cure was effected. The patient left the city in the following spring, and we have not since heard from her.

The following case is taken from Bordenave's Observations on the Diseases of the Antrum Maxillare, as published in the Memoirs of the Royal Academy of Surgery. Although in the translation, as here presented, it is considerably abridged, no important fact connected with it has been omitted.*

CASE 14th. A man, whose right superior maxillary, at the upper part, had been swollen for about three months, had, at the same time a soft tumor on the interior of the palate, which, on being pressed, caused matter to be discharged from the nostril of that side. These affections, together with tumefaction of the gums, looseness of several of the teeth, and fetid breath, induced M. Planque, under whose care the patient was placed, to suspect suppuration of the maxillary sinus, complicated with a scorbutic diathesis of the general system. The molars, which only adhered to the gums, having been extracted, matter was discharged through their alveoli. A portion of the maxillary bone was now discovered to be carious, and this, in about a month, began to loosen, and a piece of about an inch and a half long, and half an inch in width, some time after exfoliated. The tumor exteriorly disappeared; the walls of the sinus approximated, and a cicatrix ultimately closed the opening.

The details of many similar cases are on record, but it would be extending the limits of this part of our work too far to introduce them here. The history of the cases already given, will suffice to illustrate the treatment of these affections. We would, however, have given a case of mollities ossium of the walls of this cavity, had we not, while treating of ulceration of the lining membrane, quoted one in which that affection had become complicated with this.

It sometimes happens, when a very large opening has

* Another interesting case is narrated by Bordenave, which the author has given in his Treatise on the Diseases of the Maxillary Sinus, p. 115.

been formed through the inferior part of this cavity, that it does not always readily close. It is true this does not often occur, except the natural opening has become obliterated. When the parts do not manifest a disposition to unite, the practice introduced by Bordenave and Scultet, which consists in cauterizing the interior circumference of the opening, will, in most instances, prove successful. If this and all other means fail, the opening may be closed by means of an obturator of fine gold. This should be accurately fitted to the parts, and secured, by means of a broad clasp, to a molar or bicuspid tooth, and if there be none suitable on this side of the mouth, to which it can be applied, the gold should be extended to one on the opposite side. If it be necessary to replace the lost teeth with artificial ones, these may be so mounted that the plate upon which they are set, shall cover the opening into the maxillary sinus, and thus obviate the necessity of any other obturator.

CHAPTER SEVENTH.

TUMORS OF THE LINING MEMBRANE AND PERIOSTEUM OF THE MAXILLARY SINUS.

THE lining membrane and periosteal tissue of the maxillary sinus occasionally become the seat of fungous and other tumors, and in consequence of the concealed situation of the cavity, morbid productions originating in it, often make considerable progress before they attract attention; hence, the efforts of art for their cure, which might otherwise frequently be successful, in most instances prove unavailing. The presence of a tumor may give rise to all the diseases to which its osseous walls are liable, as well as to most of those incident to its soft tissues. As soon as the morbid growth has filled the sinus, it presses upon the lining membrane, excites inflammation, and sometimes ulceration, causing its secretions to become vitiated. A diseased action is communicated to the periosteum of the surrounding osseous walls, this ceases to furnish the hard tissues, with the healthy juices which they require for their preservation; the periosteum thickens, ulcerates, and is destroyed, or exudes a corrosive fluid. The bony parietes are softened or become affected with caries or necrosis, and one or more fistulous openings are formed through the cheek, alveoli, or palatine arch.

These are not the only effects that result from tumors situated in this cavity. As they increase in volume, after having filled the antrum, they gradually distend and displace its bony walls; the floor of the orbit is sometimes elevated, and the eye more or less forced from its socket; the palatine arch and alveolar ridge are depressed, the teeth loosen and drop out. When the tumor is of a

soft fungous nature, it not unfrequently escapes through the alveoli into the mouth, and after forcing the jaws asunder to their greatest extent, protrudes from it in enormous masses. Bertrandi gives the history of a case of a polypus exerescence of the antrum, which, after having destroyed the palate, anterior part of the maxillary bone, and filled the mouth, forced itself up into the orbit, elevated its roof, pressed upon the brain, and ultimately occasioned apoplexy and death. Other similar cases are on record. Mr. Cooper says there are three specimens of diseased antrum in the museum of the London University College. The tumor in two of these had "made its way from the antrum to the brain." The third was taken from a patient of his, which had died. The tumor in this case, which was of a medullary and scirrhus character, forced itself up into the orbit, displaced the eye, and, ultimately, caused the death of the patient. The same author mentions another case, the subject of which was a boy in St. Bartholomew's Hospital, who had a tumor of the antrum, which "made its way through the orbital plate of the frontal bone and cribriform plate of the ethmoid into the cranium," and though the portion of it that entered the brain was as large as a small orange, he says the boy was only in a comatose state about forty-eight hours previously to his death.

Tumors occupying the maxillary sinus do not always originate in the lining membrane or periosteum. They sometimes arise from the pituitary membrane of the nose, frontal sinus, or ethmoidal cells, and after having found their way into this cavity, augment in size, until they produce the effects just described. Some suppose that the morbid productions found here, originate more frequently in the cells of the ethmoid bone, than in the lining membrane of this cavity.*

We are disposed to believe that this opinion is not well founded, and that it has chiefly resulted from the great liability of most kinds of tumors of this cavity, to be re-

* Vide Traite des Maladies de la Bouche, t. i, p. 210.

produced after having been extirpated—which is often attributable to the continuance of the cause that gave rise to them in the first instance, or to their imperfect removal. That they do, however, sometimes originate in the ethmoidal cells, there can be no question.

It sometimes happens that tumors having their seat in the antrum, after having filled it, make their way into the nose where they acquire a size equal to, or even greater than that which they had previously attained, thus dividing themselves, as it were into two parts—one occupying the antrum, and the other one of the nasal cavities. Occurrences of this sort are not unfrequent, and they sometimes lead to the adoption of an incorrect opinion with regard to the real seat of the disease. Thus, a polypus of the antrum is occasionally mistaken for one of the nose, and the error frequently not discovered, until an attempt is made to remove it.

The character of morbid growths, in this cavity, is exceedingly variable, as much so as is the state of the constitutional health of different individuals, and the causes that give rise to them. They not only vary in their appearance and structure, but they vary in their malignancy. Some are of a healthy flesh color, soft, sensitive, but not painful, and present a smooth, regular surface; others varying in their consistence from hard to soft, and in their color from pale yellow to deep red or purple, present a rough, irregular, and not unfrequently ulcerated surface, and are more or less sensitive to the touch. Some have their origin in the mucous membrane, and others, both in this and the periosteum. Some are attached by a broad base, and others, only by a mere peduncle.

As it regards this latter description of tumors, which are usually designated by the name of polypi, their occurrence in the maxillary sinus is questioned by some writers. Sir Benjamin Brodie does not believe they ever form in this cavity; *

* Vide London Medical Gazette, for December, 1834, p. 850.

and in this opinion Mr. S. Cooper fully concurs ; but that they are occasionally met with, seems, nevertheless, to be conclusively established. A case described by M. Bertrandi in his treatise on Operative Surgery, page 369, has already been referred to ; and Bordenave, in his observations on the diseases of the antrum maxillare, gives the history of a case treated by M. Doublet. Rusch declares that he has twice seen polypus of this cavity, and Pettit, Levrette and other writers also affirm that they have witnessed polypi here.* The occurrence, then, of polypi in the maxillary sinus, although very rare, it must be admitted, does sometimes happen. Other descriptions of tumors are certainly more frequently met with in this cavity. Of these, some are of a simple fibrous, sarcomatous, or osteo-sarcomatous nature,† and when thoroughly extirpated, are seldom reproduced ; others are of a medullary, cancerous, or carcinomatous character. These last, although originating in the mucous membrane, if long neglected, are very liable to be reproduced after their removal, and generally occasion the death of the patient.

It sometimes happens that several fungi, and from opposite and various points spring up. The chances of cure, when this is the case, especially if they are of a malignant character, are greatly lessened.

Tumors of this cavity seldom grow very fast during the early stages of their formation ; but, as they enlarge, the neighboring parts become involved in the diseased action, and consequently furnish them with fluids less healthy in their qualities, and thus cause them to assume a character of greater malignancy, and generally to increase more rapidly in size.

* Vide *Traite des Maladies de la Bouche*, tom. 1, p. 212, and *sur cure des Polypes de la matrice, de la gorge, et du nez*, p. 253.

† Vide Professor Reese's *Appendix to Cooper's Surgical Dictionary*, American edition, 1842.

SYMPTOMS.

The occurrence of tumors in the maxillary sinus is rarely accompanied, previously to having obtained a size sufficiently large to fill it, by symptoms differing materially from those occasioned by many of the other affections that locate themselves here. After they have filled the sinus, the indications soon become less equivocal. Swelling of the cheek, depression of the palatine arch and alveolar ridge, loosening of the superior molar teeth of the affected side, inflammation and sponginess of the gums, elevation of the floor of the orbit, and protrusion or concealment of the eye, are symptoms which result from the presence of tumors in this cavity, but they are not peculiar to these affections alone; many of them are produced by mucous engorgement of the sinus. When to these is superadded the discharge of bloody sanies from the nose, or from one or more fistulous openings through the cheek, alveolar ridge, or palatine arch, the diagnosis will be conclusive; and the existence of a tumor in the antrum be established beyond doubt.

There are also other signs by which the occurrence of a morbid growth in this cavity may be known; as for example: dropping out of the superior molars of the affected side, and the protrusion of portions of the tumor through the alveoli.

The pain is seldom severe until the tumor has filled the cavity, except the excrescence is, from its inception, of a malignant character; as it augments in size and forces the walls of the sinus asunder, it becomes more and more severe. Sometimes, during the progress of the disease, it becomes almost excruciating. In a case of fungous hematomas of this cavity, which the author had an opportunity of witnessing in 1835, the patient was in the habit of taking upwards of two tea-spoonfuls of black drop at a time, for the procurement of ease and sleep.

In addition to the foregoing symptoms, several of the af-

fections already treated on, together with all the effects produced by them, not unfrequently result from tumors in this cavity. Inflammation and ulceration of its lining membrane, a purulent condition of its secretions, caries, necrosis, and softening of its osseous walls, seldom fail to attend some of the stages of the formation of the morbid productions under consideration. It is unnecessary to mention the symptoms peculiar to each variety of tumor, as they are given by writers on general surgery.

CAUSES.

Most writers on the affections of the maxillary sinus, are of opinion that tumors in this cavity result spontaneously, as a consequence of some specific constitutional vice, independently of local causes. We do not believe that they are ever developed spontaneously. That a bad habit of body, or some constitutional vice is necessary to the production of the affections under consideration, is very probable, but that this is capable of giving rise to them in parts uninfluenced by local irritation, we think exceedingly questionable. Having, however, already expressed our views with regard to the agency of particular habits of body and constitutional vices in the production of disease in this cavity, it will not be necessary to repeat what we have before said upon the subject. It will be sufficient to remark that most, if not all of the morbid excrescences met with, result from local irritation, favored by constitutional vices; and that both are necessary to their production.

TREATMENT.

It is only in the earlier stages of the formation of tumors in this cavity, that surgical treatment can be adopted with success, and even then, their entire extirpation is necessary. Without this, a speedy return of the disease may be expect-

ed. But, preparatory to the removal of the diseased structure, a large opening should be made into the antrum, so as to expose as much of it as possible; and with regard to the most proper place for effecting this, Deschamps recommends, when the alveolar ridge has been started, the removal of the first or second molar, and the perforation of the sinus through its socket with a "three-sided trocar of suitable dimensions." When the alveolar ridge and teeth are sound, he directs the opening to be made through the outer wall of the sinus above the ridge, and this, he thinks, on account of its being more direct, is preferable to the other mode. An opening may be easily effected in either way into the sinus, as its walls are generally so much softened as to offer but little resistance.

When the opening is made through the external parietes, the instrument recommended by Mr. Thomas Bell, for cutting away the bone after it has been exposed, is a "strong hooked knife," which is probably as well adapted to the purpose as any that can be used. Some surgeons employ strong curved scissors, but the hook knife we think preferable.

A free opening having been effected, a finger of the operator should be introduced, and the nature of the diseased structure ascertained. This done, he will be able to determine the proper procedure to be had recourse to for its removal. If the tumor partakes of the character of polypi, it may be seized with a pair of forceps, and torn away; if it be attached by a broad base, its extirpation will be most readily effected with a knife. But even with this, it is often exceedingly difficult to effect its total removal, so that it not unfrequently becomes necessary to employ the actual cautery; for, if any small portions be left behind, as has before been stated, a reproduction of the disease will generally very soon take place. When the disease has originated, or is seated in the periosteum, the cautery has proved to be the most effectual means of preventing its return. French surgeons have applied it with great success. Desault, in a

case of fungous tumor, succeeded in effecting a cure, after three applications. The root of the disease, by the employment of this, can often be destroyed, when less effectual means would fail. But it is important, when it is had recourse to, that it should have such a degree of heat, as to accomplish the object instantaneously, else the inflammation that would otherwise be excited by its application in the surrounding parts, would greatly retard, if it did not prevent, the cure. The remarks of Mr. Thomas Bell upon this subject, who says, "the white heat should be employed," are worthy of attention.

In remarking upon the bold practice of the French surgeons in the treatment of these affections, the author just quoted says, "it is worthy of our praise and imitation;" and, continues he, "the timidity which, until very lately, almost excluded the use of the actual cautery in this country, has been one cause, and that a very prevalent one, of failure in the treatment of some of these cases; but it is not so easy to account for the still more culpable dread, which has, in so many instances, prevented any attempt from being made to extirpate the disease: a degree of pusillanimity, which is at once an opprobrium on the profession and a fatal injustice to the sufferers, who, thus abandoned to the unrestrained progress of the disease, are left to perish by a lingering and most painful process, without even an attempt being hazarded for their relief."

The foregoing comparison, instituted by Mr. Bell, between the practice of the French and English surgeons in the treatment of tumors of the maxillary sinus, is certainly correct. But it is due to truth to say, that the bold practice of the former has been fully and successfully emulated by American surgeons. Dr. A. H. Stevens, Professor of Surgery in the University of New York, in 1823, in a case of fungous tumor, attached by a broad base to the lower part of the antrum, removed a large portion of the lower and anterior parts of the upper jaw. The patient recovered,

and is said to be living at the present time, 1844.* In 1841, Dr. J. C. Warren, of Boston, for a case of cephalomatous tumor of this cavity, removed the superior maxillary bone. This operation was also successful.† The same operation was performed soon after, and for the removal of a tumor of the antrum with success, by Dr. R. D. Mussey, of Cincinnati, Ohio,‡ and Dr. Fare, of Columbia, South Carolina, has performed the operation twice with success.

Thus it is perceived, that the disease under consideration not unfrequently calls for one of the most formidable operations in surgery, and that by it, many unfortunate sufferers have been snatched from the very jaws of death. The application of the cautery, notwithstanding, often becomes necessary to prevent a reproduction of the excrescence, and there are many cases in which it cannot be repressed even by this means. The result of the most thorough and best directed treatment depends on the state of the constitutional health and the nature of the disease. In depraved habits and shattered constitutions, if the tumor is of a carcinomatous character, a cure need never be expected.

The hemorrhage, during the operation for the removal of tumors of the antrum, is sometimes so profuse as to require very prompt and active means to arrest it. It may, generally, however, be controlled by the employment of compresses and suitable styptics; should these fail, the actual cautery must be resorted to.

The history of the following cases taken promiscuously from various works, will perhaps furnish a more correct idea of the methods of treatment most proper to be pursued than any description which could otherwise be given. The first three cases are taken from the *Memoirs de l'Academie Royale de Chirurgie*.§

CASE 15th. A man about thirty-five years of age, had a

* Appendix to Cooper's Surgical Dictionary, p. 30.

† Boston Medical and Surgical Journal for 1842.

‡ Western Lancet for 1842.

§ Tome 13, obs. 1, 5 and 7th, pp. 372, 387 and 424.

fleshy tumor, the size of a large pea, situated in a space formed by the decay of the first and second superior molars of the left side. This tumor caused a dull pain; it was excised, and the actual cantery applied to arrest the bleeding and destroy the remaining portions of the excrescence. It re-appeared, and three months after was double the size of the former, and impeded mastication. The two decayed teeth were loose, and the others were painful; and fetid matter escaped through the nose and mouth.

After the extraction of the two decayed teeth, M. Dubertrand, discovering that the tumor had its seat in the antrum, seized it with polypi forceps and brought the whole of it away. After the extraction of the tumor, the opening through the alveolus was large enough to admit the little finger. M. Dubertrand next destroyed such portions of the alveoli and maxillary bone as were decayed. After the extirpation of the tumor, he found it necessary to introduce a plug of cotton into the antrum, to arrest the hemorrhage that followed the operation.

The secretions of the maxillary sinus ceased to exhale an unpleasant odor; in three days they became healthy, and in less than one month, the patient was restored to health, and the opening from the mouth into this cavity was closed with firm granulations.

The tumor just described was of the simplest kind, but had it not been completely eradicated, it would, doubtless, have soon re-appeared.

CASE 16th. Acoluthus reports the case of a woman thirty years of age, who, in 1693, came to Pologne in Silesia, in search of aid for a peculiar disease of the antrum, under which she was laboring. Some time after the extraction of a tooth from the left side of the upper jaw, a small tumor appeared in its alveolus, and made such progress that in two years it attained the size of a double fist. It occupied nearly the whole cavity of the mouth, and distended the jaw to such a degree that it was feared it would rupture it.

The lower jaw was depressed, the lips could not be made to meet, and the tumor increased so fast, that in a few weeks the woman's life was despaired of—she being threatened with death from suffocation, hunger and thirst. Under these circumstances, Acoluthus determined to attempt a cure.

The tumor was very hard, and occupied the greatest part of the palatine arch; the upper teeth of the left side were in its centre. The operation was commenced by enlarging the mouth, beginning at the commissure of the lips, and passing it transversely through the cheek. This enabled Acoluthus to attack the exterior of the tumor with a curved bistoury. The excrescence was as hard as cartilage, and scarcely yielded to cutting instruments applied by a strong hand. He, however, succeeded in bringing three or four teeth, together with a portion of the superior maxillary bone. The operation as yet had extended only to the exterior half of the tumor; the other which filled the palatine fossa, he says, it was impossible to bring away. The removal of that was effected only by piecemeal, and at different times. The operation was long, laborious and very painful. The actual cautery was applied to the bleeding vessels and fungous flesh. The appearance of the patient, a few days after the operation, was such as to inspire hope for a favorable termination of the disease. The actual cautery was applied several times, and finally there was no indications of a re-appearance of the excrescence, except at the point where it had first originated. Some portions of bone were afterwards found to be carious, and the removal of these was followed by a prompt and speedy cure.

This operation is alluded to by M. Velpeau, as embracing the removal of the entire superior maxillary bone, but from the description here given, it would appear that only a small portion of the bone was taken away. The alveolar ridge and anterior parietes of the sinus is all that was removed. The history of the case, however, imperfect as it is, and the result of the treatment, proves that the resources of art

are adequate to the cure of many of the most formidable of the affections of this cavity, if they are not delayed too long.

Another case, taken from the memoirs of the Royal Academy of Surgery, is described by the author in his dissertation on the diseases of this cavity; for the particulars of which, the reader is referred to page 131, of that work.

CASE 17th. A young lady of Picardy having been exposed to the changes of weather for three years, in attending to business which required of her to be much on horseback, experienced, at the end of the first year, a chilly sensation in her left cheek; this increased, and her cheek became swollen, and her molar teeth of the affected side loosened, and two dropped out.

The swelling of her cheek increased, and she was affected with lancinating pains in that side of her face; her breath became offensive, and she lost two more teeth. Becoming alarmed, she went to Rouen to obtain medical advice. Receiving no satisfaction, she went to Paris, and applied, November 20th, 1740, to M. Croissant de Garengéot, who found her face greatly disfigured. Her mouth, he says, was on the right side, the left side of her nose much elevated, the left cheek very large, and the upper lip of the same size greatly thickened. Bluish flesh of the size of an olive occupied the alveoli of the teeth which had dropped out, the left side of the roof of the palate was thrown inwards and resembled the exterior projection of the cheek. The anterior wall of the antrum and left nasal bone, had become softened, and the whole cavity was filled with fungous flesh.

M. Garengéot commenced the operation by seizing the bluish excrescence, which had appeared through the alveoli, with a hook and cutting it away; and he says he incised transversely, every day, from within the mouth, the buccinator muscle, and brought away part of it as well as the flesh which so much augmented the size of the jaw.

The hemorrhage was so abundant that it was impossible

to proceed further with the operation. The excrescence was rapidly reproduced after each operation; these excisions were repeated seven or eight times in six weeks, and the hemorrhage, each time was very great. The seat of the disease was in the anterior of the sinus. The fungous flesh contained in this cavity was removed, as well also as some osseous projections.

The excrescence continuing to be reproduced, the patient no longer refused to have the actual cautery applied; the use of which was resorted to, twice a day, for eight days. The success, says M. Garengot, which followed this treatment, was incredible. The flesh soon took on a healthy consistence, the palatine arch returned about two-thirds to its natural situation, and the bad odor of the mouth gradually disappeared.

The application of the cautery was continued, once a day, for three weeks, and the patient did nothing more than to use a slightly stimulating and astringent gargle. On the 20th of March she returned home cured.

It is very probable that had the operation in the case just described been thorough, there would have been no return of the disease, for it is evident from the description which M. Garengot gives of the operation, that the seat of the affection was not reached until it had been repeated seven or eight times; and then, we think it very likely, not until he had recourse to the actual cautery.

The utility of the actual cautery, not only for the purpose of thoroughly destroying every remaining vestige of fungous tumors of the antrum maxillare after their removal, but also for the suppression of hemorrhage, would seem to be fully established by the result of the treatment of cases sixteen and seventeen.

The employment of arsenical preparations has, in some instances, been found highly advantageous in repressing the growth of fungous excrescences. The following case is cited by Mr. Thomas Bell as an example.*

* Anat Phys. and Diseases of the Teeth, p. 283.

CASE 18th. "James Woodley was admitted into Guy's Hospital, September 4th, 1821, for a fungous exostosis, which arose from the antrum maxillare, and made its way through the palate. After his admission he had the fungous removed two or three times, and a variety of caustic applications were afterwards made use of; notwithstanding which the tumor re-appeared. At length Sir A. Cooper, after having made an incision from the corner of the mouth outwards through the cheek, removed the tumor from a greater depth than had previously been effected. After this operation, the wound in the cheek readily healed, and the following strong solution of arsenic was daily applied to the part from whence the tumor had been removed.

℞ Arsenic, oxyd. alb. ʒ vi.
Potass. subcarb. q. s.
Aq. distillat. M. ft. solutio.

"The solution required to be diluted in the first instance on account of its occasioning him a good deal of pain; in a few days, however, he used it of the strength mentioned in the formula. It was applied regularly every afternoon, after which he did not take any food until the following day. At the time of its application he had a piece of oiled silk, of a horse-shoe shape, passed into the mouth, its sides being turned up to prevent the solution escaping into the mouth; his head then hanging down over a basin, a piece of sponge moderately saturated with the solution was applied to the disease upon the oiled silk, pressed against the part; such of the solution as was then pressed out, passed along the channel of the oiled silk into the basin over which the head was hanging, and the saliva escaped behind the oiled silk into the same utensil. He kept the sponge in this situation until it gave him considerable pain, when it was removed and the mouth carefully washed. He suffered great pain in his mouth during the period of cure; but the arsenic did not produce any other unpleasant symptoms.

This application was continued for a few weeks, at the end of which time he was completely cured ; a cavity being left in the site of the tumor, which, however, gradually became covered by a continuation of the membrane which naturally lines the palate."

The maxillary sinus is sometimes occupied by fungous tumors, originating in the alveoli of the molar teeth, or from the roots of these teeth. The following is a case which came under the observation of the author in February, 1846 :

CASE 19th. Miss L——, of Baltimore, æt. twenty-two, of a bilious temperament, called to consult us in relation to the condition of her teeth, on the 10th of February, 1846. On examination, the crowns of the first and second superior molars of the left side were found badly decayed, and which, from the destruction of the greater portion of their sockets, were much loosened. The gums on either side were much swollen, spongy and had a livid appearance ; from between the edges of which, whenever the teeth were touched, thin, fetid matter, occasionally streaked with blood and pus, was discharged. She complained of a sensation of fulness, and occasionally of slight pain in her left cheek. The affected molars had been troublesome and sensitive to the touch for nearly three years, arising, as she supposed, from a severe cold, as she suffered about that time, for near two weeks, the most violent pain in these teeth. She had several times, subsequently, been urged by her friends to have the teeth removed, but the fear of pain had prevented her from submitting to the operation.

Fearing that the diseased condition of the sockets of the affected molars had extended to the antrum maxillare, and confident that the parts immediately involved could not be restored to health while they remained in the mouth, we advised her to have them removed. After much persuasion, she consented to the operation.

The gums being separated from the teeth, we at once

grasped the first molar with a pair of forceps, and proceeded to remove it. It readily yielded to a very slight force, but the moment this was applied, a gush of blood issued from the left nostril, and the complete removal of the tooth being prevented by a fungous excrescence which had originated at the extremity of its roots, and passed up into the antrum, the true nature of the affection at once suggested itself to our mind. The tooth, after being partially removed, was liberated by cutting the excrescence.

The hemorrhage for a few minutes was profuse, but after it had partially subsided, the socket was examined, when an opening was discovered through the floor of the antrum, large enough to admit the end of the little finger—the fungous peduncle, after its separation from the roots of the tooth, having contracted, had passed up into this cavity. This was now partially explored by means of a small probe, and found to be nearly filled with a soft spongy tumor, which bled profusely from the slightest injury. Finding a portion of the floor of the antrum, back of the tooth which had just been extracted, in a necrosed condition, and partially exfoliated, we extracted the second molar, which also had a fungous excrescence upon the extremity of its roots, which passed up through an opening from the socket into this cavity, and then removed the dead bone. This occupied the space between the two teeth.

An opening was now formed through the floor of the antrum, of about an inch in length, and more than a quarter of an inch in width, which enabled us to explore the interior of the cavity more thoroughly than we had previously been able to do. The tumor, which at first had completely filled it, had, from the hemorrhage occasioned by the laceration of the vessels, become so reduced in size, that we were enabled to pass a small curved probe between it and the walls of the sinus, and by this means, to satisfy ourselves that it had no connection with any part of the cavity. There was no danger, therefore, to be apprehended of a reproduction of the excrescence after its removal, which was

easily affected, by piecemeal, with a small sharp-pointed hook, and a narrow bladed knife.

The opening through the alveolar border, into the antrum, soon closed, and the parts, in a short time, were restored to a healthy condition.

What would have been the result, in this case, had the teeth been permitted to remain, is not difficult to conjecture. The pressure of the excrescence, as it augmented in size, would have caused necrosis of the entire floor, if not of the walls of the antrum, which would ultimately have become detached and displaced, carrying it and the diseased teeth with them. But, in the meantime, other parts might have become involved in a worse and more unmanageable form of disease.

In the treatment of tumors of this cavity, it sometimes becomes necessary for their complete eradication to remove the entire superior maxillary bone, and the following is the method pursued by Mr. Liston in the performance of this formidable operation: The extent of the disease being accurately ascertained, the points of separation are decided upon. Supposing the malar bone involved, the instruments employed, *are a pair of straight tooth forceps, a full sized bistoury, copper spatula, powerful scissors, artery forceps, a small saw, and needles for interrupted and twisted suture.*

Thus armed, he commences the operation by extracting a central incisor, either on the affected side or the opposite, as the size of the tumor may require. The point of the bistoury is then carried from the external angular process of the frontal bone down to the corner of the mouth through the cheek; the incision being guided by placing the fore and middle fingers in the cavity of the mouth. A second incision is made along the zygoma, and connects with the first. The knife is now pushed through the integument to the nasal process of the superior maxilla, detaching the ala from the bone, and cutting the lip through in the middle line.

The flap is dissected up and held by an assistant; the soft parts, as the inferior oblique muscle, infra-orbital nerve, and attached to the floor of the orbit are cut, and its contents supported by a narrow bent spatula.

The section of the bone comes next in order. This is made with the cutting forceps, dividing in succession, the junction of the malar bone, the zygomatic arch, the nasal process of the superior maxilla, and then with strong scissors, after having notched the alveolar process, one blade is passed in the mouth, and the other in the nostril of the affected side, the palatine arch is cut through. At this stage, the carotid artery, if necessary, is compressed. The tumor is now turned down from its bed, and the remaining attachments divided, preserving, if possible, the palatine plate of the palate bone with the velum palati. The branches of the internal maxillary being torn and stretched may not require a ligature. The patient being now placed in a reclining posture, the cavity sponged out and examined, and all vessels, whether bleeding or not, that are seen, secured with a ligature, and the ends cut off. The space occupied by the tumor and removed structures are filled with lint, and the edges of the wound united with either the interrupted or twisted suture. No dressing is applied—plasters, bandages, etc., being thought useless. In twenty-four hours, some of the sutures are withdrawn, and plasters then applied; in forty-eight hours they are all removed, the wound at this time having adhered.

Other methods have been proposed for excision of the upper jaw. Ferguson begins his incision from the margin of the upper lip, carries it to the nostril, and along the ala to within half an inch of the inner canthus; a second incision extends from the angle of the mouth to the zygomatic process, and a third at right angles to this last, extending from the external angular process of the frontal bone towards the neck of the jaw. Gensoul lets fall a vertical incision from near the inner canthus, and divides the upper lip entirely through over the canine tooth; a transverse cut

beginning and level with the nostril, extends from this last to the forepart of the lobe of the ear. A third incision commencing about half an inch to the outer side of the external canthus, is carried down almost vertically, and touching the outer extremity of the transverse incision. Two flaps are thus formed, the one superior and dissected upwards, the other inferior and turned downwards.

Professor Warren and M. Velpeau use a single incision similar in shape, and extending from the external canthus, at its temporal margin, to the angle of the mouth. From this incision a flap is dissected upwards from the surface of the bone, the ala detached from the nose, and the whole turned upwards towards the forehead. From the same incision another flap is turned downwards sufficiently to expose the malar and maxillary bones.

The use of the saw and cutting forceps, and, if necessary, the chisel and mallet, together with the securing of the arteries by ligature, and the actual cautery—in a word, the dressing of the wound in all these different methods is nearly the same as that already described.*

There are a number of highly interesting cases of sarcomatous, carcinomatous, and other tumors of the maxillary sinus, in Jourdain's *Treatise on the Surgical Diseases of the Mouth*; some of which we had intended to introduce into this treatise, but apprehending that it would extend it to too great a length, we have concluded to omit them. A number of equally interesting cases reported in various other works,† are for the same reason excluded.

Bell's Surgery*, vol. iv, &c.

In conclusion, we would remark, that Professor Pattison proposed, in 1820, for the dispersion of fungous tumors of the maxillary sinus, tying the carotid artery. He was induced to recommend this method of treatment, from the consideration, that the "capability of action of a part, is proportioned to its vascularity, and that thus by cutting off the circulation of blood to it, the morbid growth would slough and be thrown off. He says this practice has been successful where it has been adopted in all the cases that had come to his knowledge.*

CHAPTER EIGHTH.

EXOSTOSIS OF THE OSSEOUS PARIETES OF THE MAXILLARY SINUS.

THE osseous walls of the maxillary sinus sometimes become the seat of bony tumors—a disease designated by medical writers by the name of exostosis. This, however, is not an affection peculiar to the bony parietes of this cavity ; all of the osseous structures of the body are liable to be attacked by it.

Exostosis, like many other diseases, present several varieties. It is divided, by some writers, into true and false, the one consisting of a tumor composed wholly of bone, or nearly so, and the other, of a tumor composed both of ossific matter and fungous flesh, or of a mere thickening of the periosteal tissue.* Sir Astley Cooper divides exostosis into periosteal, medullary, cartilaginous and fungous. The first consists of a deposition of bony matter on “the external surface of a bone and the internal surface of its periosteum,” and to both of which it firmly adheres. The second consists of “a similar formation, originating in the medullary membrane and cancellated structure of the bone,” this description of exostosis never attacks the walls of the maxillary sinus. By cartilaginous exostosis he means, “that which is preceded by the formation of cartilage, which forms the nidus for the ossific deposit.” Fungous exostosis he describes to be a tumor not so firm in its consistence as cartilage, but harder than fungous flesh, having interspersed through its substances spicula of bone, of a malignant char-

* Vide Dictionnaire des Sciences Medicales, t. xvi, p. 218.

acter, and dependent upon some peculiar constitutional diathesis, and action of vessels. This species of exostosis differs but little, if at all, from osteo-sarcoma.

Exostoses differ as much in shape as they do in structure. They sometimes rise abruptly from the surface of bones by a narrow and circumscribed base, projecting in large irregularly or spherically shaped masses; at other times they rise very gradually, covering a larger surface of the affected bone, but less massy and with limits less perfectly defined. An exostosis has been known to occupy the whole extent of the surface of a bone. "The whole external surface of one of the bones of the skull was found occupied by an exostosis, while the cerebral surface of the same bone was in a natural state.* Both sides and the whole thickness of bones are occasionally affected by this disease. This is what Sir Astley Cooper calls periosteal exostosis.

This disease is said to attack some bones more frequently than others. Those of the skull, the lower jaw, sternum, humerus, radius ulna, femur, tibia and bones of the carpus are the most subject to it. It also very frequently attacks, the upper jaw, and none of the bones of the body, in fact, are exempt from it.

The texture of exostosis is sometimes spongy and cellular, at other times, very dense. Dr. E. Carmichael, a distinguished surgeon and physician, formerly of Fredericksburg, Virginia, described to the writer, a few years since, an exostosis of the superior maxillary, which had, a short time before, fallen under his observation, larger than a hen's egg, and as solid as ivory. Exostosis of the roots of the teeth are always hard, and instances are sometimes met with of osseous tumors upon other bones possessed of nearly an equal degree of solidity. Exostoses of this description grow less rapidly than those which are more cellular; but they sometimes acquire a very large size. It is not, however,

* Vide American edition of Cooper's Surgical Dictionary, p. 362.

uncommon for such, after having attained a greater or less size, to cease to grow, and "remain stationary" through life, without giving rise to any very serious or unpleasant consequences.

Exostoses sometimes attain an enormous size, and especially upon cylindrical bones; very large ones, too, are frequently met with upon the maxillæ. The largest one, we believe, of the maxillary sinus, of which medical history furnishes any account, is exhibited upon a specimen of morbid anatomy, presented in 1767, by M. Beaupreau, to the French Academy. A description and drawing of this tumor is contained in the Memoirs of the Royal Academy of Surgery, but we have no account of the history of its formation, nor of the symptoms that resulted from it. The tumor occupies the whole of the right maxillary sinus, and several of the neighboring bones are involved in it. It is very large near its base and projects from the lower part of the orbit, forward and downward, six inches. Its largest circumference is said to be one foot. The upper part of the maxillary bone, says Bordenave, projects on the side of the orbit, and straightens the cavity; the *os unguis* is included in the mass of the tumor, and is represented as being nearly effaced. The nasal bones of the left side are displaced, and the right nostril entirely closed up, and the exostosis projects so much on the left side as to be nearly underneath the malar bone. The inferior part of the maxillary bone, says our author, is so extended near its base, that it inclines obliquely to the left, and the pterygoid apophyses of this side are larger than those of the other. The malar bone is described as being involved in the upper and external part of the exostosis, which extends to the left maxillary bone.

Exteriorly, says Bordenave, the tumor had a smooth and polished appearance, its upper part was very hard; inferiorly its substance had become thinner, was wanting in some places, and the interior of the exostosis was exposed. The substance of the bone was spongy and porous, and in

appearance, not unlike pumice stone. The walls were thick, and measured in some places one inch.*

From this brief description, taken from one given of it by Bordenave, some idea may be formed of the dimensions and appearance of this enormous and most remarkable exostosis.

A case of exostosis of each antrum, is described by Sir Astley Cooper, both of which forced themselves up into the orbits, and pushed the eyes from their sockets. One made its way into the brain, and caused the death of the patient.†

Mr. Thomas Bell does not believe in the occurrence of "true exostosis upon the bony parietes" of this cavity, but too many examples have presented themselves, to leave any room for doubt upon the subject. Although none may ever have fallen under his own immediate observation, there are many well authenticated cases on record—the details of some of which we shall presently give. Apart from these, we think it would be difficult to assign any sound reasons for supposing that the osseous walls of this cavity should be more exempt from the disease than other bones of the body.

SYMPTOMS.

The attacks of exostosis of the walls of the maxillary sinus, are generally so insidious, that the presence of the disease is not, for a long time, even suspected. When it results from venereal vice, Boyer says, it is preceded by acute pain, extending at first to almost every part of the affected bone, but which afterwards confines itself to the affected portion. When it is occasioned by scrofula, the same writer tells us, it is attended by a duller and less severe pain; the symptoms of exostosis resulting from causes purely local, such, for example, as a blow, are very similar.‡ These signs are common to the disease wherever

* Vide *Memoires de l'Academie Royale de Chirurg.*, t. xiii, obs. xii, p. 412.

† *Surgical Essays*, part i, p. 157.

‡ *Traite des Maladies Chirurgicales*, t. iii, p. 545.

it may be situated, and when it is seated in the maxillary sinus, they do not distinguish it from many of the other affections that occur here; for they are often produced by them, as well as by exostosis. Furthermore, the disease not unfrequently gives rise to other symptoms attendant upon several of the other affections of this cavity, so that previously to the distension of its walls, it may be confounded with inflammation of the lining membrane or sarcomatous or other tumors. After it has filled the sinus, or very considerably thickened its exterior walls, it will cause them to offer a firmer resistance to pressure than any of the other diseases of this cavity. When, therefore, they have become distended, if they are firm and unyielding to pressure, the presence of exostosis may be inferred.

C A U S E S .

There is a difference of opinion among writers on the diseases of bones, with regard to the causes of exostosis. Certain constitutional diseases, such as "scrofula and lues venerea," are thought by some to give rise to the affection. That the last of these diseases is favorable to its production, is, we believe, admitted by all; but Sir Astley Cooper declares that no evidence has yet been adduced to prove that the former is ever concerned in its production. Others impute the disease to local irritation produced by contusions, fractures, &c. It is probably dependent upon both local and constitutional causes, and that neither, independently of the other, is capable of producing it.

T R E A T M E N T .

A variety of plans of treatment have been recommended for this disease, and Bordenave assures us it may be cured, if suitable remedies are applied before it has acquired much solidity. Assuming that it sometimes results from constitutional causes, he directs that the treatment should be

commenced by the employment of such means as are indicated by the nature of the vice with which the patient may be affected. If a venereal vice be present, the use of mercurial medicines are recommended. The author last mentioned, says, he has known it to be successfully treated with mercury. Topical applications, such as fomentations and cataplasms, have also been found serviceable. Boyer advises poultices of linseed meal, and a decoction of the "leaves of henbane and nightshade." Iodine and mercury have been employed, but not, we believe, with any decided advantage. Sir Astley Cooper thinks the best internal remedy is "oxymuriate of quicksilver, together with the compound decoction of sarsaparilla." We believe, with Boyer, that a dispersion of an exostosis can never be effected. Its progress may, perhaps, be partially arrested, but we do not believe, that it is ever taken up by the absorbents. It is not advisable to remove an exostosis unless it continues to augment and is likely to become dangerous, or is productive of serious inconvenience.

When, therefore, the remedies which have been mentioned, after having been thoroughly tried, prove unsuccessful, the tumor should be fully exposed; first, by the dissection of the gum and other soft parts from the exterior walls of the sinus, and, second, by the perforation of this cavity with a trephine, or such other instrument as can be most conveniently employed. This part of the operation, though simple, should be conducted with care. If the tumor is large and attached by a very broad base, its removal will sometimes prove more difficult, yet by means of suitable constructed saws, scissors, knives, &c., it may, in most instances, be easily effected. An external wound through the cheek should always, if possible, be avoided.

The method of operating, however, will be best understood by a description of that pursued in the two following cases. The first was treated by Dr. B. A. Rodrigues, dentist, of Charleston, S. C., and reported by him for the *American Journal of Medical Sciences*.

CASE 21st. "On the 14th of August, 1837, Charity, a servant woman of Mrs. Miller, called on me to ascertain whether I could afford her any relief in her wretched condition. She had been laboring under incessant and agonizing pain in the antrum highmorianum of the right side, which she regarded as the consequence of the impaired condition of the teeth. On this supposition, she had several of them extracted, without any appreciable abatement of her sufferings. Yet, deluded with the belief that some one of the remaining teeth was the secret agent of all she suffered, she persisted in having more extracted. Still, the evil continued, the suffering was unabated, the cause undetected; and to add to the depression of her hopes, and the aggravation of her ills, a purulent discharge oozed from the empty sockets of the affected side. She again had recourse to medical advice, hoping that this phasis of her malady might lead to some indications that would relieve her; at least, that it might reveal its hidden sources, its condition, and its prospects of being remediable. And here, for the first time, was it suggested that the antrum was in an unsound state.

"It was at this moment, under these circumstances, that she applied to me to perform an operation, which her medical adviser declared to be indispensable. At first, I imagined it to be an abscess from the cavity from which the pus was discharged, from the strange sensations experienced, and from the greater frequency of this disease over others peculiar to this part, I inserted a trocar into the socket of the second molar, and instead of the gush of matter I had expected, the passage of the instrument was intercepted by a hard, dense, impregnable substance. The existence of an exostosis now forced itself on me. To make assurance doubly sure, I had access to several of my medical friends, among whom was Dr. Geddings. On examination of the part, the consideration of the symptoms, the obstinate nature of the disease, they concurred with me in opinion, that an exostosis was present, and that the sole indication of re-

lief was its extirpation. Accordingly, on the 18th of August, the above gentlemen, with several others of the profession, were present when I proceeded to perform the operation. With a common scalpel, I dissected away the gum from the canine tooth to the last molar, raised the flap which it made from the alveolar process, and with a trephine opened into the cavity. Success was easier than had been anticipated, in consequence of the carious condition of the process, which was so general on the affected side, as to reach from the second incisor anteriorly to the pterygoid process posteriorly. In the loss of substance, the external parietes of the cavity shared, so that the bony tumor which filled up and occupied it, could be readily reached. The trephine was applied, the cavity enlarged, and the exostosis removed. It measured in circumference three inches, was light, and cancellated on its surface, but dense and more resisting in its more internal layers. There was little or no hemorrhage to delay the operation, or any application to arrest it. After removing every spiculum of diseased bone, and cleansing out the cavity, the flap was replaced, and to nature was entrusted the cure. Granulations sprouted up in full luxuriance, and in the short period of four weeks, the woman was in the enjoyment of excellent health.”*

That the foregoing was a case of true exostosis of the maxillary sinus, does not admit of doubt, and it is to be regretted, that more of the early history of the disease, and the circumstances connected with its developments, are not known. They might, perhaps, lead to a correct explanation of the causes that gave rise to it. The presence of local irritants in the immediate vicinity of this cavity, is proven by the fact that the patient's teeth were in a diseased condition, but to what extent they may have contributed to the production of the exostosis it is impossible to determine, since we are not furnished with any information concerning the state of her general health. She may have been affected with some constitutional vice, or peculiar habit of body,

* American Journal of Medical Science.

whereby the osseous structures of the system were predisposed to affections of this description, requiring only the presence of some local irritant to induce the morbid action necessary to their development. That such predisposition did exist, and that such action was excited by the irritation produced by the diseased teeth, we believe, would appear, if all the circumstances connected with the previous history of the case could be ascertained.

When the connection of the exostosis is such as to prevent its complete removal, the application of the actual cautery to any remaining portions, will prove serviceable, by causing such parts to be exfoliated. The history of a case is related by M. Bordenave, treated by M. Runge, in which a portion of the exostosis was left, and which ultimately caused the death of the patient. This would probably have been prevented had an exfoliation of the remaining diseased portions of bone been brought about by an application of the actual cautery.

CASE 22nd.* The subject of this case was a man 33 years of age. He had been for a long time afflicted with a tumor in the region of the right antrum. It depressed the palatine process of the maxillary bone and the palate bone of the affected side in such a manner as to restrict the movements of the tongue, while on the other side it pressed against the floor of the orbit so as to cause a protrusion of the eye. Anteriorly, it had elevated a portion of the maxillary and malar bones which covered it, and extended to the most dependent part of the nose, whilst posteriorly it extended as far as the posterior mouth. Its effects upon the lateral parts were nearly the same as those which it had exerted upon the others.

After having exposed the anterior parietes of the antrum, M. David saw from below upwards to the uppermost part of the projection of the tumor, which was of spherical shape, and nearly three inches in diameter, and, after having elevated that part, he discovered the tumor, which was white

* Vide Memoires de l'Academie Royale de Chirurg. t. xiii, obs. xi, p. 408.

and hard ; although spongy, and bearing a strong resemblance to soft agaric, it occupied the maxillary sinus. It had changed the form of this cavity and increased its dimensions to an extraordinary degree. The greater portion of this hard osseous substance, although firmly adhering to almost every part of its bony envelop, was by a persevering employment of various means, such as the crotchet, elevator, surgeon's rasp, &c., detached by M. David. In doing this, he inflicted some injury upon the floor of the orbit, and to some portions which still adhered to the palatine process of the maxillary bone, he applied the actual cautery, which was repeated several times.

An opening was formed by this operation four and a half inches deep, and from right to left, of more than three inches, but a cure was, notwithstanding, speedily effected by it, which, had the use of the cautery been omitted, would not perhaps have been successful.

Exostosis of the maxillary sinus often gives rise to other morbid conditions of this cavity, the remedial indications of which should be properly attended to, as should also those of any constitutional affection, vice, or habit of body that the patient may be laboring under at the time.

When the exostosis is not complicated with any other disease of the cavity, the restorative energies of nature, after its removal, will generally be all that is required to complete the cure.

CHAPTER NINTH.

WOUNDS OF THE OSSEOUS PARIETES OF THE MAXILLARY SINUS.

THE walls of the maxillary sinus are sometimes fractured by blows and pierced by sharp-pointed instruments. Fauchard mentions a case, in which a canine tooth had been driven up into it.* This is an accident that rarely happens. The instance here alluded to, is, we believe, the only one on record; and, as might be supposed, it was followed by severe pain, and ultimately gave rise to a tumor upon the cheek near the nose, and three fistulous openings, from which fetid matter was discharged. The sinus having been opened, and the tooth taken from it, a cure was at once effected.

It often happens when the walls of the sinus are fractured from a blow or other mechanical violence, that portions of the bone and foreign bodies are driven into the cavity, and which, remaining there, become a constant source of irritation to the lining membrane, and, not unfrequently, a hidden cause of other and more malignant forms of disease. Bordenave describes the case of a French officer, who had the walls of the maxillary sinus fractured by a fragment of a bomb. Dressings were applied to the wound, but it did not heal, and upon examination sometime after by M. Allouel, several pieces of bone and a splint which nearly filled the cavity were found. These were removed, but a cure was not immediately effected; a fistulous opening still remained, and it was not until a long time after, when

* *Le Chirurgien Dentiste*, tom. i, page 391.

another splinter came away, that the external opening healed. The same writer mentions the case of a man who had a nail forced head foremost, by the discharge of a gun, into his right cheek and maxillary sinus. The opening became fistulous, and although the point of the nail was subsequently discharged, it was not until M. Faubert had removed the remaining part, that the fistula closed.

Wounds of the antrum are almost always complicated with fractures of the osseous parietes, so that the effects resulting from them are more to be dreaded than those which would be produced simply by the penetration of a sharp instrument.

TREATMENT.

The nature and extent of the injury inflicted, should determine the treatment most proper to be adopted for wounds of this cavity. Complicated as they in most instances are by the presence of extraneous substances, the removal of these constitutes the first, and not unfrequently, the only remedial indication. This should never be neglected. When any extraneous bodies, or portions of bone, have been forced into the sinus, they should first be all carefully removed. The external wound may next be dressed with adhesive slips to prevent the formation of an unsightly cicatrix. If constitutional symptoms supervene, they should be met with appropriate remedies.

The following interesting case of a wound of the maxillary sinus, inflicted with a dirk-knife, reported by R. S. Welten, student of medicine, and treated by W. H. Donne, M. D., of Louisville, Ky., is taken from the *Western Journal of Medicine and Surgery*.

CASE 23d. "Schuti, a gardener, aged 42 years, a native of Germany, in a rencontre with an athletic man, on the 3d of May, 1840, was struck with a dirk-knife, which entered about an inch above the right superciliary arch, passed

through the corresponding eyelid downwards and backwards, evacuating the humors of the eye, and penetrating the antrum. The globe of the eye was divided by a vertical incision, through which the aqueous humor escaped; the iris was extensively detached at the ciliary margin, and could be partially seen through the transparent cornea—its surface being somewhat obscured by small coagula. The hemorrhage was slight and easily controlled by moderate pressure. The patient complained of intense pain in the temple and cheek of the wounded side shooting deep into the orbit. Three points of interrupted suture were used to approximate the edges of the divided eye. Lint, saturated with laudanum and warm water, constituted the dressing.

“May 4th. Some tumefaction in the eyelid; pulse 110; tongue coated and dry; skin hot; patient had spent a very restless night. Ordered following medicine, tart. emetic, gr. i.; sulph. magnesia, $\frac{3}{4}$ ss.; to be dissolved in one-half pint of water, and a table-spoonful to be taken every half-hour, until nausea is induced—after which the interval may be increased.

“May 5th. Bowels freely evacuated; pain less; skin moist; pulse 90 and soft. From this period until the wound healed—the space of three weeks—no constitutional symptoms of an untoward character occurred. The patient, however, contended that a portion of the knife-blade remained in the roof of his mouth. But, on the most careful examination, no foreign body could be detected.

“On the 10th of August, 1842, Mr. Schuti called and requested Dr. Donne to examine his mouth, stating that for six months past he had been annoyed by a rough, projecting substance, which some person had informed him was a piece of dead bone, but which he believed to be the point of the knife, that had been driven down into the bone by the violence of the blow. On looking into the mouth, a small black speck was discernable about one-half inch from the interval between the first and second molar teeth. The parts adjacent were somewhat tumefied and inflamed. Dr. Don-

ne made several attempts to extract this body with a pair of common dissecting forceps, but found it immovably fixed in the substance of the bone. By dissecting around it with a bistoury, down to the palate process of the superior maxillary bone, he was enabled to get a firmer hold, and, with a pair of curved tooth-forceps, succeeded in removing a fragment of the blade, one and one-fourth inches in length, and three-fourths in width at the widest part; the extraction was not effected without considerable violence, and was attended with extreme suffering. The fragment came out with an audible snap, which induced those present to suppose, at first, that it had been broken; but on inspecting its surfaces closely, they were found similarly oxydized, and wanting the lustre which a recent fracture had presented. Upon probing the aperture, through which the fragment had been extracted, no other piece could be detected. This opening would scarcely admit the curved probe which Dr. Donne passed into the antrum, in order to satisfy himself, that the whole of the foreign body was removed. The next day there was a slight discharge from the aperture, though the patient has suffered very little pain since the operation."

The foregoing is certainly one of the most singular cases of which we have any account, and the most remarkable circumstance connected with it is, that no more injury should have resulted from the presence, for so long a time, in the maxillary sinus, of the portion of the blade of the knife that had been broken off. In the cases previously noticed, as reported by Bordenave, disease of the mucous membrane of the antrum, and the discharge of fetid sanies resulted from the presence of the foreign bodies in this cavity. The same effects were also produced in the case described by Fauchard, of the canine tooth which had been forced up into the antrum.

CHAPTER TENTH.

FOREIGN BODIES IN THE MAXILLARY SINUS.

THAT foreign bodies are sometimes admitted into the maxillary sinus through wounds penetrating its exterior parietes, has already been shown, but that they should gain access to it in any other way, would seem almost impossible. The smallness and peculiar situation of the opening which communicates with it, is such, one would think, as would preclude the introduction of extraneous substances of any kind through it, yet they have been found here when they could not have gained admission in any other way. There are several well authenticated cases on record in which worms have been found in this cavity. The case mentioned by Bordenave, in the Memoirs of the Royal Academy, of a diseased maxillary sinus, from which several worms were at different times discharged, does not prove that they obtained admission into it through the nasal opening, and thus, as some writers have conjectured, gave rise to the disease with which it was affected. In this case, a fistulous opening from the cavity had existed for a long time previously to the discharge of the worms, and it is very probable that they introduced themselves through this opening. A cause sufficient to have produced the disease in the sinus had been operating for two years, immediately preceding its manifestation. The patient, during the whole of this time, was affected with pain in the superior teeth of the affected side.

Deschamps, says his colleague of la Charité Hospital,

found a worm in the maxillary sinus of a soldier, whom he was dissecting, four inches long; and the same writer informs us that a similar example is furnished in the *Journal of Medicine*. The particulars of a case which came under the observation of Mr. Heysham, physician, of Carlisle, taken from a work entitled "*Medical Commentaries*," are contained in Cooper's *Surgical Dictionary*. The subject of this case was a strong woman, sixty years of age, who was in the habit of taking a great deal of snuff. She was affected for a number of years with severe pain in the region of the maxillary sinus, which "extended over one side of the head." She was never entirely free from this pain, but it was greater in cold than in warm weather, and for the purpose of obtaining relief, she had been twice salivated, and had taken various anodyne medicines. The pain, however, instead of being mitigated by these means, became more severe. Her teeth on the affected side were all extracted, and as a last resort the maxillary sinus was perforated. This for several days did not give any relief. Injections of bark and "elixir of aloes," were thrown into it, and "on the fifth day a dead insect" of more than an inch in length and as thick as a "common quill," was removed from this cavity.

Instances of the introduction of insects or foreign bodies of any description into the antrum, through the nasal opening, fortunately, are so exceedingly rare, that the *Memoirs of Medicine* do not furnish more than four or five well established examples.

The signs indicative of the presence of insects or foreign bodies in the maxillary sinus, are so obscure, that the fact can only be ascertained by perforating the cavity and by examination of its interior. Some say that foreign bodies here cause an itching, crawling or tickling sensation in the substance of the cheek. This is an uncertain diagnosis, for such sensations are not unfrequent in the region of this cavity. That they sometimes cause great pain, is proven

by the history of the case related by Mr. Heysham, the particulars of which we have just noticed.

The proper remedial indication for foreign bodies in the antrum, is their removal. When insects are discovered here, injections of oil and tepid water are recommended. This constitutes all the treatment necessary to be employed in cases of this kind.

PART SIXTH.

MECHANICAL DENTISTRY.

PART SIXTH.

MECHANICAL DENTISTRY.

By mechanical dentistry is meant the art of constructing and applying *artificial teeth, artificial palates, and appliances for the correction of irregularity in the arrangement of the natural teeth.* But in treating upon this part of our subject, we shall, for the present, confine ourself to the first, or a description of the various methods of constructing and applying artificial teeth, reserving what we may have to say upon artificial obturators and palates for the seventh and last part of our work, and as the various appliances employed for the correction of irregularity of the teeth have already been described, it will not be necessary to refer to the subject again.

Before entering upon a description of the method of procedure in the construction of artificial substitutes for the natural teeth, and the manipulations connected therewith, we shall offer a few general remarks on the subject of such substitutes—the substances of which they are composed—the means employed for their retention in the mouth, and the surgical treatment required preparatory to their application.

CHAPTER FIRST.

ARTIFICIAL TEETH.

CONTRIBUTING as the teeth do to the beauty and agreeable expression of the countenance—to correct enunciation—and by the function of mastication which they assist in performing, to the health of the whole organism, it is not surprising that their loss should be considered a serious affliction, and that art should be called upon to replace such loss with artificial substitutes. So great, indeed, is the liability of the human teeth to decay, and so much neglected are the means of their preservation, that few persons reach even adult age without losing one or more of these invaluable organs. But, happily for suffering humanity, they can now be replaced with artificial substitutes so closely resembling the natural organs, as to be readily mistaken for them, even by the most critical and practiced observer. Although there is a perfection in the works of nature that can never be equalled by art, artificial teeth are now, nevertheless, so constructed, as to subserve, in many cases, at least to a great extent, the purposes of the natural organs. They are also worn, when properly adjusted, without the slightest discomfort—the patient, after they have been in the mouth a few days, being scarcely conscious of their presence.

The construction and insertion of artificial teeth, is an operation, which, though acknowledged to be of great importance, and performed by every one having any pretensions to a knowledge of dentistry, is, unfortunately, but little understood by the majority of practitioners. The mouth is frequently irreparably injured by their improper

application. A single artificial tooth badly inserted, may cause the destruction of the two adjacent natural teeth, and if the deficiency thus occasioned be unskillfully supplied, it may cause the loss of two more, and in this way all the teeth of the upper jaw are sometimes destroyed.

The utility of artificial teeth depends upon their being properly constructed, and correctly applied. As much skill and judgment are required for the practice of this, as for the other branches of the art. A knowledge of the anatomy and physiology of the mouth, of its various pathological conditions, and therapeutical indications is as essential to the mechanical as it is to the operative dentist, and to correct information upon these subjects, should be superadded ability to execute with the nicest skill and most perfect accuracy, the various pieces of mechanism required in dental prosthesis.

There are difficulties connected with the insertion of artificial teeth which none but an experienced dentist has any idea of. Besides, those of properly constructing and applying them in such a manner, as that they may be easily removed and replaced by the patient, and at the same time, be securely fixed in the mouth, and productive of no injury to the parts with which they are associated, there are sometimes others equally difficult to overcome. For example: the loss of a tooth in one jaw, is generally followed by the gradual protrusion from its socket of the one with which it antagonized in the other, so that if the loss of the former be replaced with a substitute of equal size, it will often strike against the latter at each occlusion of the mouth, and prevent the other teeth from coming together. This tendency of the teeth in one jaw to proturde, is always in proportion to the number lost in the other; and if not soon counteracted by the replacement of the latter with artificial substitutes, it often gives rise to an obstacle to their proper application, requiring no little ingenuity and tact to overcome.

But, notwithstanding the triumphs of Mechanical Dentistry, and the high state of excellence to which it has arrived,

there never was a time when so much injury was inflicted, and suffering occasioned by artificial teeth, as at present, and resulting, too, from their bad construction and incorrect application. That such should be the case, when there are so many scientific and skillful dentists in every city, and in many of the villages of the country, may seem strange, but the fact is nevertheless undeniable.

The information obtainable from works on mechanical dentistry, was until recently exceedingly limited; and it is surprising, that from the number who have written on the diseases and loss of the teeth, this subject should have received so little attention. Fauchard, Bourdet, Angermann, Maury, Delabarre, Koecker, Lefoulon, Brown, and a few others, are all who have given it any thing more than a passing notice; and the works of but few of these writers contain anything like explicit directions upon the subject. Delabarre's *Mechanical Dentistry* was, at the time of its publication, a work of much merit. The various methods adopted at that period, for the construction and application of artificial teeth, are accurately and minutely described in it—together with the advantages and disadvantages of each. But, however perfect the work may then have been, it does not furnish the information required upon the subject at the present day. And still more deficient in correct information are nearly all the other French works.

Among the English writers, Koecker is almost the only one, except Robinson, a more recent author, who has described correctly the principles upon which artificial teeth should be applied. His "*Essay on Artificial Teeth, Obturators and Palates*," contains much useful and valuable information. It does not, however, contain a description of the manner of constructing a dental substitute, preparatory to its application; yet, to one capable of executing the various manipulations required in this department of practice, it is very serviceable. But as this ability can only be acquired by a regular apprenticeship, Dr. K. perhaps, thought that a more minute description was unnecessary. There

are many practitioners, however, who are in other respects competent, that have not enjoyed this advantage, or, at least, not in the mechanical department, and, consequently, it is to be regretted, that he has not entered more into detail upon the subject.

But most of the deficiencies that exist in the last named work, were supplied up to 1844, by Dr. Solyman Brown, in his series of papers on Mechanical Dentistry, published in the American Journal of Dental Science. These papers are illustrated with numerous cuts, and constitute the best treatise upon the subject that had appeared up to the time of their publication. But numerous and important improvements have subsequently been made in this department of practice. These will all be described in their proper place.

We shall enumerate some of the different kinds of dental substitutes that have been employed since the commencement of the present century. We shall also notice briefly, the principal methods that have been adopted in their application, before entering upon a minute description of those practiced at the present time. Great improvements have been made in dental prosthesis since the publication of the first edition of this work.

CHAPTER SECOND.

SUBSTANCES EMPLOYED FOR ARTIFICIAL TEETH.

THERE are certain qualities which it is highly important that artificial teeth should possess. They should be durable in their nature, and in their appearance resemble the natural organs, with which they have often to be associated.

The kinds of teeth that have been employed, since 1830, are :

1. Human teeth.
2. Teeth of neat cattle, sheep, &c.
3. Teeth carved from the ivory of the elephant's tusk, and the tooth of the hippopotamus.
4. Porcelain teeth.

HUMAN TEETH.

As it regards appearance, and in a dental substitute this is an important consideration, human teeth are preferable to any other, and when used for this purpose, they should be of the same class as those, the loss of which they are to replace. The crowns only are employed, and if well selected, and securely adjusted, the artificial connection with the alveolar ridge cannot easily be detected.

The durability of these teeth when thus employed, depends on the density of their texture, the soundness of their enamel, and the condition of the mouth in which they are placed. If they are of a dense texture, with sound and perfect enamel, and are placed in a healthy mouth, they will last from eight to twelve or a greater number of years. The difficulty, however, of procuring these teeth, is generally so

great, it is seldom that such as we have described, can be obtained, and even when they can, the mouth in half the cases in which artificial teeth are placed, is not in a healthy condition ; its secretions are vitiated and of so corrosive a nature, that they often destroy them in less than four years. We have even known them to be destroyed by caries in two, and in one case in fifteen months.

A human tooth, artificially applied, is more liable to decay than one of equal density having a vital connection with the general system, for the reason, that its dentinal structure is more exposed to the action of deleterious chemical agents. But of all the animal substances employed for this purpose, human teeth are unquestionably the best. They are harder than bone, and being perfectly protected by enamel, and consequently more capable of resisting the action of corrosive agents.

Many object to having human teeth placed in their mouth, under the belief that infectious diseases may be communicated by them. But there is no good foundation for such fear. The purifying process to which they are previously submitted, precludes the possibility of the communication of disease. When the practice of transplanting teeth was in vogue, occurrences of this sort were not unfrequent, but since that has been discontinued, it has never happened. But, the prejudices of some against human teeth are so strong, that it is impossible to overcome them.

The difficulty of procuring them, and the high price they command, have also induced many dentists to profit by this popular prejudice, and to employ other substitutes.

TEETH OF CATTLE.

Of the various kinds of natural teeth employed for dental substitutes, those of neat cattle, are, perhaps, after human teeth, the best. By slightly altering their shape, they may be made to resemble, very closely, the incisors of some persons, but a configuration similar to the cuspids cannot be

given to them; and in the majority of cases they are too white and glossy to match very closely human teeth. The contrast, therefore, which they form with the natural organs should constitute, if they were in all other respects acceptable, an insuperable objection to their use. This has been too much disregarded, both by dentists and patients. Indeed, many of those who need artificial teeth, wish to have them as white and brilliant as possible.

But there are other objections to the use of these teeth. In the first place they are only covered anteriorly with enamel, and, in the second, their dentinal structure is less dense than that of human teeth, and consequently they are more easily acted on by chemical agents. They are, therefore, less durable, seldom lasting more than from two to four years. Another objection to their use is, they can only be employed in very few cases, for their nerve cavities are so large, that by the time they are reduced to the size of the incisors, they become exposed, and by the time these fill up with ossific matter, their crowns are so much worn away that they are too short, except in cases where short teeth are required. It is seldom, therefore, that they can be used as substitutes for human teeth.

IVORY OF THE TUSKS OF THE ELEPHANT AND HIPPOPOTAMUS.

Artificial teeth made from the ivory of the tusk both of the elephant and hippopotamus have been sanctioned by usage from the earliest periods of the existence of this branch of the art; but we must not hence conclude that it has been approved by experience. On the contrary, of all the substances that have been used for this purpose, this is certainly the most objectionable.

The ivory of the elephant's tusk is decidedly more permeable than that obtained from the hippopotamus. So readily does it absorb the buccal fluids that, in three or four hours after being placed in the mouth, it becomes completely

penetrated with them. Consequently, it is not only liable to chemical changes, but also to become offensive, and when several teeth, formed from it, are worn, they affect the breath to such a degree as to render it exceedingly offensive. But on account of its softness, teeth are easily shaped from it, but not being covered with enamel, they soon become dark, and give to the mouth a most filthy and disgusting appearance. Fortunately, however, in the United States, elephant's ivory is rarely used for artificial teeth.

The ivory of the tusk of the hippopotamus is much firmer in its texture than that obtained from the elephant; and, being covered with a hard, thick enamel, teeth may be cut from it, which, at first, very closely resembles the natural organs. There is, however, a peculiar *animation* about human teeth, which those made from this substance do not possess. These, moreover, soon change their color, assuming first a yellow and then a dingy bluish hue. They are, also, like those just mentioned, very liable to decay. We have in our possession a number of blocks of this sort, taken from the mouths of different individuals, some of which are nearly half destroyed.

But there is another objection to teeth made of this substance, which, even were there no other, would be sufficient to condemn its use. It is, that they, like those formed from elephant's ivory, give to the air returned from the lungs, an insufferably offensive odor, which cannot be corrected or prevented. They may be washed half a dozen times a day, and taken out and cleansed again at night, but it will still be grossly perceptible; and, although it may be worse in some mouths than others, no one who wears teeth made of this substance is entirely free from it.

To one whose attention has never been directed to the subject, it would be astonishing to observe the effects produced upon the breath by wearing two or three of these teeth.

PORCELAIN TEETH.

The manufacture of porcelain teeth did not for a long time promise to be of much advantage to dentistry. But by the ingenuity and indefatigable exertions of a few, they have, within the last twenty-five years, been brought to such perfection as almost to supersede any other kind of artificial teeth.

The French, with whom the invention of these teeth originated, encouraged their manufacture by favorable notices; and the rewards offered by some of the learned and scientific societies of Paris contributed much to bring it to perfection. They were still, however, deficient in so many particulars, that they received the approbation of very few of the profession, and then only in some special cases. It is principally to American dentists that we are indebted for that which the French so long labored in vain to accomplish.

A want of resemblance to the other teeth, in color, translucency, and animation, was the great objection urged against porcelain teeth; and, had not this been obviated, it would have constituted an insuperable objection to their use. Until 1833, all that were manufactured had a dead opaque appearance, which rendered them easy of detection, when placed alongside of the natural teeth, and gave to the mouth a sickly aspect. But so great have been the improvements in their manufacture, that few can now distinguish any very marked difference between them and the natural organs.

The advantages which mineral teeth possess over every sort of animal substance, are numerous. They can be more nicely fitted to the mouth, and worn with greater convenience. They do not absorb its secretions, and, consequently, when proper attention is paid to their cleanliness, they do not contaminate the breath, or become, in any way, offensive. Their color never changes. They are not acted

on by the chemical agents found in the mouth, and hence the name *incorruptible*, which has been given them. The objections that have been urged to their use, are, want of congeniality between them and the mouth, they being better conductors of caloric than bone, and, consequently, more liable to become cold when exposed to the air, etc.; but these have so little foundation, that, when compared with the advantages they confessedly possess, they must be regarded as unworthy of consideration.

CHAPTER THIRD.

DIFFERENT METHODS OF APPLYING ARTIFICIAL TEETH.

THE methods of applying artificial teeth are, first, on the roots of the natural teeth ; Second, on plate with clasps ; Third, with spiral springs ; Fourth, by atmospheric pressure. The peculiar advantages of each of these methods we shall now proceed to point out, and the cases in which they are particularly applicable.

ARTIFICIAL TEETH PLACED ON NATURAL ROOTS.

This method of securing artificial teeth, was, until recently, on account of its simplicity, more extensively practiced than any other, and, under favorable circumstances, is, unquestionably, the best that can be adopted. If the roots on which they are placed are sound and healthy, and the back part of the jaws supplied with natural teeth, so as to prevent those with which the artificial antagonize from striking them too directly, they will subserve the purposes of the natural organs more perfectly, than any other description of dental substitute. When thus placed, they rest on a firm basis, and if properly fitted and secured, their connection with the natural roots cannot easily be detected. But, unfortunately, the incisors and cuspidati of the upper jaw, are the only teeth which it is proper to replace in this way.

The insertion of an artificial tooth on a diseased root, or on a root having a diseased socket, is almost always followed by injurious effects. The morbid action already existing in the root, or its socket, is aggravated by the opera-

tion, and often caused to extend to the contiguous parts, and, sometimes, even to the whole mouth. Nor is it always proper to apply a tooth immediately after having prepared the root. If any irritation is produced by this preparatory process, the tooth should not be inserted until it has wholly subsided. The neglect of this precaution not unfrequently gives rise to inflammation of the alveolo-dental periosteum and alveolar abscess.

Although this method of securing artificial teeth has received the sanction of the most eminent dental practitioners the world has ever produced, and is certainly the best that can be adopted for replacing the loss of the six upper front teeth ; yet, on account of the facility with which the operation is performed, it is often resorted to under the most unfavorable circumstances, and in consequence of which, has been, undeservedly, brought into discredit.

The efforts of the economy for the expulsion of the roots of the bicuspid and molar teeth, after the destruction of their lining membrane, are rarely exhibited in the case of roots of teeth occupying the anterior part of the mouth. This circumstance has led us to believe, that the roots of these teeth receive a greater amount of vitality from their investing membrane, than do the roots of those situated farther back in the mouth, and that, though the amount of living principle with which they are thus supplied, is inconsiderable, yet it is sufficient to prevent them from becoming manifestly obnoxious to their sockets.

The admission of this hypothesis can alone account for the fact to which we have just alluded, for it is well known that a dead root is always productive of injury to the surrounding parts, and that nature calls into action certain agencies for its expulsion. Therefore, attaching a tooth to a completely dead root, is manifestly improper ; but the fangs of the front teeth are rarely entirely deprived of vitality, and hence, after the destruction of the lining membrane, they often remain ten, fifteen, and sometimes,

twenty years, without very obviously affecting the adjacent parts.

The manner of preparing a root and inserting a tooth on it will hereafter be described.

ARTIFICIAL TEETH ATTACHED TO A PLATE WITH CLASPS.

This method of applying artificial teeth, is, perhaps, in favorable cases, with the exception of the one just noticed, and one to be hereafter described, the best that can be adopted. By this means, the loss of a single tooth, or of several teeth, in either or both jaws, may be supplied. A plate may be so fitted to an aperture in the dental circle, and secured with clasps to the other teeth, as to afford a firm support to six, eight, ten, or even twelve artificial teeth.

Teeth applied in this way, when properly constructed, will last for several years, and sometimes during the life of the individual. But it is necessary to their durability, that they should be correctly arranged, accurately fitted, and substantially secured to the plate, and that the plate itself be properly adapted to the gums, and attached to teeth firmly fixed in their sockets.

Gold is the best metal that can be employed for the plate and clasps. For the former, the gold should be from twenty to twenty-one carats fine, and from eighteen to nineteen for the latter. If gold of an inferior quality is used, it will be liable to be acted on by the secretions of the mouth. Platina would, perhaps, answer the purpose as well as gold; but there are so few in this country who understand working it, that the getting of it out into plate, and such other forms as are required, is attended with much difficulty and inconvenience.

The plate should be thick enough to afford the necessary support to the teeth; but not so thick as to be clumsy or inconvenient from its weight. The clasps generally require to be about one-third or one-half thicker than the plate, and

sometimes double the thickness. The gold used for this purpose, is sometimes prepared in the form of half round wire; but, in the majority of cases, it is preferable to have it flat, as such clasps afford a firmer and more secure support to artificial teeth than those which are half round; they also occasion less inconvenience to the patient, and are productive of less injury to the teeth to which they are attached.

Artificial teeth, applied in this way, may be worn with the greatest comfort, and can be taken out and replaced, at the pleasure of the person wearing them; and it is important that they should be very frequently cleansed, to prevent the secretions of the mouth that get between the plate and gums, and the clasps and teeth, from becoming vitiated and irritating the soft parts, and corroding the teeth and tainting the breath. This precaution should, on no account, be neglected. Great care, therefore, should be taken to fit the clasps in such a manner as will admit of the easy removal and replacement of the piece, and, also, that they may not exert any undue pressure upon the teeth to which they are applied. If they press too hard upon them, they will excite inflammation in the alveolo-dental periosteum, and the gradual destruction of their sockets will follow as a natural consequence.

ARTIFICIAL TEETH WITH SPIRAL SPRINGS.

The only difference between the method last noticed, of applying artificial teeth, and the one now to be considered, consists in the manner of confining them in the mouth. The former is applicable in cases where there are other teeth in the mouth to which clasps may be applied—the latter is designed for confining a whole set, and part of a set, where neither clasps, nor any other means, can be conveniently employed for their retention in the mouth.

When plates with spiral springs are used, the teeth are attached to them in the same manner as when clasps

are employed; but instead of being fastened in the mouth to other teeth, they are kept in by means of the spiral springs, one on each side of the artificial denture between it and the cheeks, passing from one piece to the other.

Spiral springs were often employed for confining only a lower set in the mouth, and sometimes for only parts of sets. When a number of teeth in the back part of the jaws are required, and there are no teeth in the mouth to which clasps can be applied, capable of affording sufficient support, spiral springs were formerly much used. Various other kinds of springs have been used, but none seem to answer the purpose as well as these. When they are of the right size, and attached in a proper manner, they afford a very sure and convenient support. They exert a constant pressure upon the artificial pieces, whether the mouth is opened or closed. They do not interfere in the least with the motions of the jaw, and, although they may at first seem awkward, a person will soon become so accustomed to them, as to be almost unconscious of their presence.

ATMOSPHERIC PRESSURE, OR SUCTION METHOD OF APPLYING ARTIFICIAL TEETH.

The method last described, of confining artificial teeth in the mouth, is often inapplicable, inefficient and troublesome, especially for the upper jaw, and it is in such cases, more particularly, that the atmospheric pressure, or suction method, is valuable. It was, for a long time, thought to be applicable only for an entire upper set, because it was supposed that a plate sufficiently large to afford the necessary amount of surface for the atmosphere to act upon, could not be furnished by a piece containing a smaller number of teeth. Experience, however, has proven this opinion to be incorrect. A single tooth may be mounted upon a plate presenting a surface large enough for the atmosphere to act upon for its retention in the mouth, but, when only a part

of an upper set is required, it is often necessary to secure the piece by means of clasps. For a like reason, it was thought that the narrowness of the inferior alveolar ridge would preclude the application of a plate to it upon this principle, and in this opinion the author participated, but he has succeeded so perfectly in confining lower pieces by this means, that he now never finds it necessary to employ spiral springs.

The principle on which this plan is founded, may be simply illustrated by taking two small blocks of smooth flat marble, and exhausting the air from between them—the pressure of the atmosphere on their external surfaces, will enable a person to raise the under block, by lifting the upper. In a similar manner, a gold plate, or any other substance, impervious to the atmosphere, and perfectly adapted to the gums, may be made to adhere to them.

The firmness of the adhesion of the plate or base to which the teeth are attached to the gums, depends on the accuracy of its adaptation. If this is perfect, it will adhere with great tenacity, but if the plate is badly fitted, or becomes warped in soldering on the teeth, its retention will often be attended with difficulty. It is also important that the teeth should be so arranged and antagonized, that they shall strike those in the other jaw all the way round at the same instant. This is a matter that should never be overlooked, for if they meet on one side before they come together on the other, the part of the plate or base not pressed on, will be detached, and by admitting the air between it and the gums, will cause it to drop.

The application of artificial teeth on this principle, has been practiced for a long time ;* but the plates formerly used, were ivory instead of gold, and could seldom be fitted with sufficient accuracy to the mouth to exclude the air ; so

* To the late Mr. James Gardette of Philadelphia, belongs the honor and credit of the discovery of the practicability of applying artificial teeth upon this principle. To him, also, belongs the credit of being the first to employ clasps for the retention of dental substitutes.

that, in fact, it could hardly be said that they were retained by its pressure. Unless fitted in the most perfect manner, the piece is constantly liable to drop, and the amount of substance necessary to leave in it, renders it so awkward and clumsy, that a set of teeth mounted upon a base of this material can seldom be worn with much comfort or satisfaction; and, besides, ivory absorbs the fluids of the mouth so readily, that after being worn for a few weeks it becomes exceedingly offensive.

The firmness with which teeth, applied upon this principle, can be made to adhere to the gums, and the facility with which they can be removed and replaced, renders them, in many respects, more desirable than those fixed in the mouth with clasps. But, unless judgment and proper skill are exercised in the construction of the teeth, a total failure may be expected, or at least, they will never be worn with satisfaction and advantage.

There were few writers, at the time of the publication of the first edition of this work, who had even adverted to this mode of applying artificial teeth. Drs. L. S. Parmly and Koecker had each bestowed on it a passing notice. The former, in alluding to the subject, thus remarks: "Where the teeth are mostly gone in both, or in either of the jaws, the method is, to form an artificial set, by first taking a mould of the risings and depressions of every point along the surface of the jaws, and then making a corresponding artificial socket for the whole. If this be accurately fitted, it will, in most cases, retain itself sufficiently firm, by its adhesion to the gums, for every purpose of speech and mastication."*

It has not, until recently, been thought expedient to apply parts of sets upon this principle, nor did we, for a long time, believe the pressure of the atmosphere and capillary attraction would give to a lower set, because of the narrowness of the alveolar ridge of the inferior maxillary, sufficient

* *ractical Guide to the Management of the Teeth*, pp. 138-'9.

stability to render it at all serviceable, but experience has fully demonstrated its practicability.

Dr. Koecker tells us, that he has "been completely successful in several instances, in the application of sets for the upper jaw in this manner ;" and he says, they "should be made either with a gold plate mounted with natural or artificial teeth, or of one piece of hippopotamus' tooth."* Having already stated the objections that exist to the use of this substance, we cannot join with Dr. K. in its recommendation. At the time when we first substituted the gold plate for it, we had not seen his late work on artificial teeth, and, consequently, was not aware that the use of metal for a base had ever before been recommended.

Upon the ordinary method of applying artificial teeth on this principle, considerable improvement has been made since 1845. By constructing the plate with an air chamber or cavity, so that when the air is exhausted from between it and the parts against which it is placed, a vacuum is formed, and it adheres with greater tenacity to the gums than a base fitted simply to them.

Other methods have been resorted to for the retention of artificial teeth, but as they have long since been abandoned, a description of them is rendered unnecessary.

* Koecker on Artificial Teeth, p. 92.

CHAPTER FOURTH.

SURGICAL TREATMENT OF THE MOUTH PREPARATORY TO THE APPLICATION OF ARTIFICIAL TEETH.

THE condition of the mouth is not sufficiently regarded in the application of artificial teeth, and to the neglect of this, the evil effects that often result from their use, are frequently attributable. No artificial appliance, no matter how correct it may be in its construction and in the mode of its application, can be worn with impunity in a diseased mouth. Of this fact, every day's experience furnishes the most abundant proof. Yet there are men in the profession, so utterly regardless of their own reputation and the consequences to their patients, as to wholly disregard the condition of the mouth, and are in the constant habit of applying artificial teeth upon diseased roots and gums, before the curative process, after having extracted the natural teeth, is half completed.

The dentist, it is true, may not always be to blame for omitting to employ the means necessary for the restoration of the mouth to health. The fault, oftentimes, is with the patient. There are many, who, after being fully informed of the evil effects which must of necessity result from such injudicious practice, still insist on its adoption. But the dentist, in such cases, does wrong to yield his better informed judgment to the caprice or timidity of his patient, knowing, as he should, the lasting, pernicious consequences that must result from doing it. If he is not permitted to carry out such plan of treatment as may be necessary to put the mouth of his patient in a healthy condition, previously

to the application of artificial teeth, he should refuse to render his services.

Dr. Koecker, in treating upon this subject, says, "There is, perhaps, not one case in a hundred, requiring artificial teeth, in which the other teeth are not more or less diseased and the gums and alveoli, also, either primarily or secondarily affected. The mechanical and chemical bearing of the artificial teeth upon such diseased structures, naturally becomes an additional powerful aggravating cause of disease, already in a sufficient state of excitement, even if the teeth are mechanically well contrived and inserted; if, however, they are not well constructed, and are inserted with undue means or force, or held by too great or undue pressure, or by ligatures or other pernicious means for their attachment, the morbid effects are still more aggravated, and a general state of inflammation in the gums and sockets, and particularly in the periosteum, very rapidly follows. The patient, moreover, finds it impossible to preserve the cleanliness of his mouth; and his natural teeth, as well as the artificial apparatus, in combination with the diseases of the structures, becomes a source of pain and trouble; and the whole mouth is rendered highly offensive and disgusting to the patient himself, as well as to others."*

The first thing, then, claiming the attention of the dentist, when applied to for artificial teeth, is to ascertain the condition of the gums and of such teeth as may be remaining in the mouth. If either or both are diseased, he should at once institute such treatment as the circumstances of the case may indicate, but as this has been described in a preceding place, it is only necessary now to refer the reader for directions upon the subject, to what is there said.

When artificial teeth are to be secured in the mouth in any other way than on roots, sufficient time should elapse before their insertion, for the completion of all those changes that follow the treatment which is usually necessary in such

* Vide Koecker's Essay on Artificial Teeth, pp. 27, 28.

cases ; otherwise, instead of being worn with comfort, they will be a source of constant irritation. If they are applied too soon, they will lose their adaptation to the gums. We have now in our possession a number of parts of sets, which, from having been prematurely applied, and the changes in the shape of the parts on which they rested, that followed their insertion, pressed so unequally on the gums, that their removal became absolutely necessary for the relief of the irritation and pain they occasioned. The persons from whose mouths they were taken assured us, that at the time of their application they fitted very accurately, and were worn for a short time with comfort.

It is often necessary to wait from eight to fifteen months after the removal of the natural teeth, for the completion of the changes which take place in the alveolar ridge after such operation. In the meantime, if necessary, the patient may be supplied with a temporary substitute.

CHAPTER FIFTH.

MANNER OF PREPARING A NATURAL ROOT AND SECURING AN ARTIFICIAL CROWN TO IT.

PREVIOUSLY to the preparation of a natural root for the reception of an artificial tooth, the remaining teeth and gums, if diseased, should be restored to health. This done, such portion of the crown, as may not have been previously destroyed by caries, should be removed with an oval or half-round file.

The usual method of performing this part of the operation, consists in cutting the tooth about three-fourths off with a file, and then to remove it with a pair of excising forceps. But the forceps should not be applied until the tooth has been cut with a file on every side, nearly to the pulp cavity, and even then great care is necessary to prevent jarring, or otherwise injuring the root. When too large a portion of the crown is clipt off suddenly with excising forceps, the concussion is often so great as to excite inflammation in the socket of the tooth, and sometimes to shatter the root.

When excising forceps are used, they should be strong, so as not to spring under the pressure of the hand, with cutting edges about an eighth of an inch wide.

After the removal of the remaining portion of the crown, the nerve, if still alive, should be immediately destroyed, by introducing a silver or iron wire, or some other small sharp-pointed instrument, up to the extremity of the root, giving it, at the same time, a quick rotary motion. It is important that the instrument used for this purpose, if it be of metal, should be soft and yielding, otherwise, any sudden motion of the head of the patient might break it in the tooth.

Some recommend destroying the nerve by the introduction of a hot wire into the canal of the root, but as this is very liable to produce irritation in the surrounding tissues, the other method is preferable.

The nerve having been destroyed, the remainder of the operation will be painless. The root may now be filed off a little above the free edge of the gum, with an oval or half round file.* The exposed extremity of the root, after having been thus filed, will present a slightly arched appearance, corresponding with the festooned shape of the anterior margin of the gum.

After having completed this part of the operation, the natural canal in the root should be slightly enlarged with a burr-drill, or a broach prepared for the purpose. The canal thus formed in the root for the pivot should never exceed the sixteenth part of an inch or a line in diameter, and a quarter or three-eighths of an inch in length.

If from any peculiar constitutional susceptibility there is reason to apprehend inflammation of the alveolo-dental membrane, the insertion of the tooth may be delayed a few days for the subsidence of any irritation which may have been occasioned by the preparation of the root, but it rarely happens that the operation is followed by any unpleasant effects, unless this has previously lost its vitality by the spontaneous disorganization of the nervous pulp. In this case, an outlet may be made by cutting a groove on the side of the pivot, or in some other way, for the escape of any matter which may form at the apex of the root. Dr. Maynard believes that the irritation in most cases, arises from an accumulation of acrid matter in the upper part of the root, and that by filling the natural canal above the terminus of the pivot, up to the extremity, it may generally be prevented. This should always be done.

After having prepared the root, an artificial crown of the right shape, color and size, is accurately fitted to it. It

* The file employed for this purpose should be of the best quality, and double or cross-cut and rather coarse than otherwise.

should touch every part of the filed extremity of the root, and made to rest firmly upon it, and at the same time be in an exact line with the circle of the other teeth. If the tooth is only fitted anteriorly, an opening will be left between it and the root posteriorly, which will serve as a lodgement for foreign matter, and the substitute will also have a less secure support. Nor should the new tooth press against the adjoining teeth, or strike its antagonist before the other teeth come together.

The canal in the root, and that in the artificial crown, should be directly opposite to each other. When the crown of a natural tooth is used, the proper place for the pivot is indicated by the pulp cavity, but in porcelain teeth the hole is not always in the centre.

When the latter are used, one should be selected of the proper length, width and thickness. It should be as nearly as possible the shade of the adjoining teeth, and it would be preferable to have it even a shade darker than any lighter, as in the former case the contrast would be less perceptible than in the latter. If necessary to make any change in the

shape, it may be readily effected on a small grindstone, or an emery or corundum wheel or slab. A great number of grinding apparatuses have been invented for this purpose. Some are very simple in their construction, consisting of a single wheel turned with a crank, others are more complex in their arrangement: but the object may easily and readily be accomplished with any now in use. Those of the simpler construction are kept by most instrument makers, from whom they can be procured. The one represented in Fig. 153, which may be readily secured to a table, will, perhaps, answer the purpose as well

FIG. 153.

as any now in use. It occupies but little space, and although moved with a crank, with the hand, will, if the wheel is good, cut away a tooth very rapidly. But for fitting porcelain teeth to plates, a wheel moved by a foot-lathe, in the manner to be hereafter described, will be found preferable to the one represented here; or a small hand lathe, recently invented by Mr. Pratt, dentist, of Baltimore, may be used. In the absence of a grinding wheel, a corundum slab may be employed.

When the crown of a natural tooth is used, any change which it may be necessary to make in its shape, is made with a file.*

The artificial crown may be secured to the root by means of a pivot made of wood or metal; when the latter is employed, gold or platina is preferable to any other, inasmuch as silver or any baser metal is liable to be oxydized by the fluids of the mouth. If wood is used, it should be of the best quality of well seasoned white hickory, as this possesses greater strength and elasticity than any other that can be procured in this country. After being reduced to near the size of the orifice of the cavity in the artificial tooth, it should be forced through a smooth hole, of the size of that, in a piece of ivory, bone, steel, or some other hard substance, for the purpose of compressing its fibres as closely together as possible. Thus prepared, one end is forced into the cavity in the artificial crown, and the projecting part cut off about a quarter or three-eighths of an inch from the tooth, and this, after being reduced to the size of the orifice in the root, is inserted in it; pressure is now applied with the thumb and finger of the operator, to the tooth, and the pivot forced up into the canal of the root until the two come together. The part of the pivot going

* To obviate the difficulty sometimes experienced in making a perfect joint between the root and crown, Dr. E. Townsend, of Philadelphia, has recently invented two very excellent instruments, consisting of an oval and hollow file—the former fitting exactly into the latter. With the first he files the root, and with the other, the base or part of the crown to be fitted to it.

into the root, should never be so large as to require any other pressure than that which can be applied with the thumb and fore-finger, as the swelling of the wood will soon render it sufficiently tight to hold it firmly in its place. The practice of driving a pivot up with a hammer, as is often done, is a bad one. It is apt to cause inflammation and suppuration of the soft tissues about the apex of the root.

A porcelain tooth with a wood pivot, previously to insertion, presents the appearance represented in Fig. 154.

It sometimes becomes necessary to remove the artificial crown, and in doing this, the pivot often remains in the root. For the removal of this, the forceps represented in Fig. 155, invented by Dr. W. H. Elliott, will be found very useful. With this instrument the pivot may be re-

FIG. 155.

moved from the root without jarring it in the least, or exerting any extractive force upon it. The manner of applying and using the instrument will be readily understood by examining the above cut.

FIG. 156.

When a metallic pivot is used, the end going into the artificial crown may be fastened in either of the following ways, namely, first, by cutting a screw on it, either with a file, or passing it through a screw plate; the cavity in the crown should next be filled with a wooden tube, and the pivot then screwed into it. Second, by filling the cavity in the crown with pulverized borax, moistened with water, inserting the end of the pivot into it, which should be large enough to fill the cavity, placing several small pieces of solder around it, and applying heat to the tooth by means of a blow-pipe and lamp until it fuses and flows down around it into the tooth. The solder, by adapting itself, when in a state of fusion, to the rough walls of the cavity in the crown of the tooth, will prevent the pivot from loosening or coming out. The projecting part of the pivot should be about half an inch in length, square and pointed. The cavity in the root, which requires to be deeper for a metallic than for a wood pivot, should be filled with wood, having a small hole through the centre. Into this, the end of the pivot is introduced and forced up, until the tooth and root come firmly together. The appearance of a porcelain tooth, prepared with a metallic pivot, for insertion in the manner as just described, is shown in Fig. 156.

FIG. 157.

But when a metallic pivot is used, a plate-tooth is preferable to one made expressly for a pivot. The manner of attaching a pivot to the former, is as follows: the root is first prepared; after which, an impression is taken in wax; from this, a plaster cast is made, and from the latter, metallic casts. This done, a piece of gold plate, large enough to cover the root, should be swaged up between the metallic casts, a plate tooth of the proper size, shape and color, is then fitted to the root, backed with gold, and soldered to the plate previously fitted to the root, and to the upper or convex surface of this last,

and immediately beneath the canal in the root, a gold pivot is attached. But for the manner of conducting these various processes, the reader is referred to a succeeding chapter. A front and side view of a tooth thus prepared is shown in Fig. 157.

A pivot, consisting of gold encased in a thin layer of wood, constitutes about as secure a means of attachment as can be employed. It is prepared in the following manner: the gold is first made into wire of the proper size, and passed through a screw-plate. A hole is then drilled lengthwise into a piece of well seasoned hickory, as far as required for the length of the pivot. Into this the wire is screwed, and then cut off close to the wood, which is reduced with a file or knife, to the size of the orifice in the artificial crown, into which it is firmly forced. The projecting part of the wood is trimmed down to the size of the tube in the root, to the termination of the wire, and cut off, when the tooth is ready for insertion.

The wood prevents the gold from enlarging the cavity of the root, or that of the artificial tooth; and at the same time, by the swelling of this encasement, the pivot is firmly retained in both.

There is some diversity of opinion with regard to the best kind of pivots. Some prefer wood, others metal. Dr. Fitch, on this subject, observes: "The metallic pivots are far better than any other; and their only objection is, that they are apt to wear the tooth that is placed upon them, and the stump in which they are inserted; and so much so do they have this effect, that we are induced to use pivots of wood. This last has the advantage if perfectly seasoned, of swelling in the stump, by the moisture which they absorb; and, in this way, become very firm. The advantages and disadvantages of the two kinds, are, perhaps, nearly balanced."

To the use of wood, Dr. Koecker is decidedly opposed. "The pivots," says he, "should be made only of fine gold or platina; every other metal, such as brass, copper, silver,

and even inferior gold, are highly objectionable, being more or less liable to corrode, and thus become injurious to the other teeth and the general health. There is, however, a practice which is still more improper, namely, the use of pivots made of wood ; these pivots, after insertion, considerably expand, from the moisture of the mouth, and consequently remain perfectly firm in the roots for several years, which deceive not only the patient, but the dentist also, and induces them to consider the case very successful, until they at last find that the root is either split by the swelling of the pivot, or nearly destroyed by the rapid decay of the wood in the cavity, which, by its chemical and mechanical irritation, is very apt to produce very serious inflammation, and other affections of the gums and sockets ; and not the least objection, the disagreeable breath, which must be an unavoidable concomitant of this practice."

Again on the insertion of pivoted teeth, Dr. K. in another place adds : "I have made it an universal rule to insert the tooth in such a manner, that the patient should be capable, after receiving the necessary instructions, to remove it, and replace it, at pleasure ; for this purpose, I have found it best, and most effectual, to wind a little cotton round the pivot, which should be filed somewhat rough, previous to its insertion into the fang."

The description here given of the effects supposed to be produced by a wood pivot, is, perhaps, somewhat exaggerated. If made properly of good wood, it is no more liable to produce irritation, and to affect the breath, than gold wrapped with cotton, or one made of any other metal. The fact that wood pivots remain firmly in the roots for several years, ought rather to be considered as a recommendation, than an objection ; and with us, we must confess, it would go far towards determining our preference in their favor : for the frequent removal and replacement of a pivoted tooth, greatly tends to hasten the destruction of the root, and to irritate surrounding parts.

As a general rule, not more than two roots should be prepared at one sitting, though sometimes four or even six may be prepared without incurring any risk. Fig.

FIG. 158.

158 represents the roots of the four upper incisors, prepared for the reception of artificial teeth, and the teeth armed with wood pivots, ready to be inserted.

When a tooth is attached by any of the ordinary modes of pivoting, the walls of the canal in the root, are, of necessity, exposed to the action of the fluids of the mouth, and, consequently, are gradually softened and broken down, so that in the course of a few years a larger pivot will be required, and this, too, after awhile, will have to be replaced with one still larger, until, finally, the root is destroyed. This destructive process proceeds more rapidly in some cases than in others, according as the root is hard or soft, and as the secretions of the mouth are in a healthy or vitiated condition.

But this may be prevented by introducing a hollow gold screw for the reception of the pivot. This protects the walls of the canal against the action of corrosive agents, and a root thus prepared, will support an artificial crown more than twice as long as when prepared in the ordinary way. The operation, however, is more tedious and expensive, but it is far more valuable.

For the preparation of a tooth in this manner, the following is the method of procedure. First, the crown of the natural tooth is removed, the nerve, if alive, destroyed, and the canal in the root enlarged in the manner as before directed. Second, a screw tap, slightly larger than the canal in the root, is then introduced for the purpose of cutting a screw on its inner walls. Third, a screw is then cut on a piece of hollow gold wire, of the size of the screw tap, by passing it through a screw plate, but during this process the hollow in the wire is filled with another wire to prevent injury. This done, it may be screwed into the root about a

quarter of an inch, the wire on the inside of it is then withdrawn, and the lower or protruding extremity filed off even with the root, with a very fine file. Fourth, an artificial tooth is now selected, of the right size, shape and color, and fitted to the root, after which a gold pivot is fixed in it in the manner as before directed, of the exact size of the hollow in the screw, and to the length of which it should also correspond. Having proceeded thus far, the operation is completed by applying the tooth to the root. The pivot being of the size of the hollow in the cylindrical screw, but little pressure is required to force the one into the other.

The stability of a tooth secured in this manner, is as great if the pivot be of the proper size, as one inserted by any of the other methods, and it may be removed, cleansed, and replaced at the pleasure of the patient. When the walls of the canal are so much enlarged by decay as to have formed a large conical shaped cavity in the lower extremity of the root, the upper end of the hollow or cylindrical screw will only take effect. In this case the space between the lower extremity and the walls of the root, are thoroughly filled with gold before the wire on the inside is withdrawn; after which the tube and extruding portions of the gold are filed off even with the root, and polished before the artificial tooth is applied.

The hollow wire is made by wrapping a piece of thin gold plate round a wire of the size of that to be used for the pivots. It is then drawn through a hole in a wire-plate. The inner wire is then removed, and the seam in the other soldered. But hollow wire may be procured of the proper size at much less expense than it can be made by a dentist, and with this every practitioner should be supplied.

It sometimes happens that the natural root, instead of occupying a vertical position in the jaw, passes up obliquely, so that if the pivot connecting the artificial tooth to it be straight, the latter will either overlap one of the adjoining teeth or project forwards or point towards the interior of the

mouth. To obviate this, an angle should be given to the pivot, immediately at the point of junction between the tooth and root. A little practice will enable the operator readily to overcome a difficulty of this description.

Again, it sometimes happens that cases are met with presenting a still more formidable difficulty ; as for example, when the root is situated behind the circle of the other teeth, and to obviate which, a different kind of tooth, and an entirely different course of procedure is necessary. In a case of this sort, after having prepared the root, an impression of the parts are taken in wax, from which a plaster model is obtained, and from this two metallic casts. Be-

FIG. 159.

tween these last a gold plate extending just far enough back to cover the root and forward to form a line with the outer circle of the teeth. To the superior part of the plate covering the root, and directly beneath the cavity in it, a gold pivot, about three-eighths of an inch long, is soldered, and to the anterior part of it a plate tooth of the right size, shape, and shade, is attached. A piece of hollow wood or a hollow gold screw, as before described, is now introduced into the root, and into this the gold pivot is forced.

FIG. 160.

A side view of a porcelain tooth, mounted on a plate with a pivot, for insertion in the manner here described, is represented in Fig. 159, and in Fig. 160 a back view is shown. It is a substitute, as will be perceived by the engraving, for the right superior central incisor.

A description of the manner of obtaining an impression with wax, plaster, &c., of procuring a plaster model, metallic casts, of fitting a plate and attaching teeth to it, and finishing a piece, will be hereafter described. It is not necessary, therefore, to dwell upon this part of the subject here.

But before we proceed to do this, it will be proper to offer a few remarks on the manner of refining and alloying gold, making it into plate, springs and solder.

CHAPTER SIXTH.

MANNER OF REFINING AND ALLOYING GOLD—MAKING PLATE, CLASPS, SPRINGS, ETC., FOR ARTIFICIAL TEETH, AND SOLDER SUITABLE FOR UNITING THE DIFFERENT PARTS OF A PIECE OF DENTAL MECHANISM.

GOLD, as has already been stated, is the best metal which can be employed in connection with artificial teeth, mounted in the ordinary way, because it is the only one capable of resisting the action of the secretions of the mouth, except platina, which, as regards indestructibility, answers equally well, but the heat required to fuse the latter, is greater than can be obtained by the means employed for melting the former, consequently, if it were used for purposes of this sort, it would be at a great sacrifice, as the scraps and filings removed in working it into the proper forms, would be of little value, or at any rate, they could not readily be re-converted into plate. It would not, therefore, be a matter of much economy to substitute the use of this metal for that of gold.

Although the manner of refining, alloying and manufacturing gold into plate, solder, &c., may not be regarded as coming properly within the province of the dentist, yet, as he often experiences great difficulty in procuring them of the right quality, a brief description of these several processes will not prove unacceptable to the members of the profession. Gold in its pure state, or when free from alloy, is too soft and yielding to serve as a suitable support for artificial teeth, and if it contains too much, or an improper alloy, it will either be tarnished or blackened by the secre-

tions of the mouth, or rendered too brittle for dental purposes. It is of the utmost importance that the gold used in connection with artificial teeth, should be of the proper fineness, and possessed of the requisite ductility. To secure these qualities, it is necessary to know the kind and quantity of metal with which it is alloyed before it is made into plate or the forms necessary for the purposes for which it is to be employed, and when this cannot be previously ascertained, it should be first refined, and afterwards properly alloyed.

The scraps and filings removed in shaping and reducing to their proper size and form the various pieces of gold used in the construction of a piece of dental mechanism, are apt to become mixed with base metals, such as iron from the wearing of files, and, occasionally small particles of lead, or tin. If these are melted with and permitted to remain in the gold, they will destroy its ductility, and render it unfit for a base or support to artificial teeth. The first of these metals is less objectionable than either of the others, and may always be removed, before the gold is melted, with a magnet, but to free it perfectly from the others, it will sometimes be necessary to refine it in the manner presently to be described. A two-thousandth part of tin or lead destroys the ductility of gold, and even the exposure of it to the fumes of red hot tin or lead, renders it exceedingly hard and brittle. Antimony, or bismuth, when mixed with gold, exerts upon it a very similar effect.

Platina, united with gold in certain proportions, while it has the effect of hardening the latter metal, does not materially affect its ductility, but the affinity of the alloy for oxygen is so great, that it is readily acted upon by nitric acid. But for this, the two metals combined in the proportion of fifteen parts of gold to one of platina, would form an exceedingly useful alloy for the construction of spiral springs. But for the reason just mentioned, it cannot be safely used for this purpose, as the septic (nitrous) acid of the mouth, would, in most cases, be likely, in a short time,

to corrode and destroy the springs. That this combination of these two metals should be thus easily acted on by an agent incapable of acting on either, when in a separate state, may appear somewhat remarkable, but it is, nevertheless, true. The color of gold, even by the combination of this small quantity of platina with it, is rendered much whiter than when in its pure state.

In view, then, of the importance of having gold, which is to be placed in the mouth, of the right quality, every dentist, who has connected with his practice a mechanical laboratory, should have the necessary fixtures for melting and working this metal into the various forms required for dental purposes. The principle of these are, a small furnace, crucibles, ingot moulds, an anvil and hammers, a rolling mill, a plate-gauge, draw-plate and bench, for drawing wire, &c. These will hereafter be described.

MANNER OF REFINING GOLD.

It is not our intention, in describing the manner of refining gold, to enter into a minute detail of the various methods employed for assaying this metal, but to point out, as briefly as possible, the manner of separating it from the several metals with which it is most frequently combined.

The method usually employed by assayers for separating gold from silver, is, to roll the alloy out into very thin plates, and put it in nitric acid; this will dissolve most of the silver, and leave the gold behind in the form of a brown or black calx. This, by heating, will acquire the color of gold. But this method will not succeed, unless the quantity of silver be equal to two or three times that of the gold. When the quantity of gold is greater than that of the silver, the most of the former may be separated from the latter, by solution in nitro-muriatic acid. But a perfect separation of the two metals will not be effected in either case. In the first, a residuum of silver will remain united with the undissolved gold, and in the second, a residuum of gold will remain with

the undissolved silver. The remaining silver may be removed by melting the gold with twice its weight of sulphuret of antimony. This may be done with a strong heat in a covered crucible, and after the gold has been kept in a state of fusion for some thirty or forty minutes it should be poured out into an ingot mould, and separated from the antimony which will lie at the top. It may be necessary to melt it in this way two or three times, adding, each time, a less quantity of antimony; and at the last melting, a current of air, from a pair of bellows, should be thrown upon the surface of the fused metal to evaporate the antimony, and after the vapor ceases to escape, a little refined nitrate of potassa and sub-borate of soda should be thrown into the crucible. It should then, in a few minutes, be poured out, and if it cracks in hammering or rolling, it should be again melted, and a little more nitrate of potassa and sub-borate of soda thrown on it.

There is another process for refining gold, employed in some of the mints, called cementation. It consists in first rolling the gold out into exceedingly thin plates, then placing it with a mixture of four parts of brick-dust, one of sulphate of iron, calcined to redness, and one of chloride of soda, in a crucible. A bed of this mixture, or cementing powder, is first placed in the bottom of the crucible; the gold is then put in and covered with it. The crucible is covered with another crucible, the joints well luted with clay, and exposed to a heat gradually raised to a red heat, at which elevation of temperature, it should be kept from twenty to twenty-four hours. The crucible is now removed from the fire, the top broken off, and after the latter has cooled, the gold may be separated from the cement and washed with hot water, or what is still better, boiled in hot water.*

The kind of furnace employed for melting gold may be very simple, such, for example, as is used by gold and silversmiths, or the one invented by Dr. Somerby, in connec-

* See Chemistry of Arts, vol. ii, pp. 545-6 and 550-1.

tion with his concentrated blow-pipe. But in the absence of either of these, a furnace similar to the one used by the Ceylonese goldsmiths may be substituted. This consists of a small low earthen pot, filled with chaff, or saw-dust, on which a little charcoal fire is made, which is excited with a small bamboo blow-pipe, about six inches long, the blast being directed through a short earthen pipe or nozel, the end of which is placed at the bottom of the fire.* By this simple contrivance, a most intense heat, greater, it is said, than is required for melting gold or silver, may be obtained.

For separating copper, tin, lead or zinc, from gold, the following simple method may be adopted; put the gold in a clean crucible, covered with another crucible, having a small opening or hole through the top; lute the two together with clay, place them in a bed of charcoal in the furnace, ignite the coal gradually; afterwards increase the combustion by means of a current of air from a pair of bellows, such as are usually used in connection with small furnaces; after the gold has melted, throw in several small lumps of nitrate of potassa (saltpetre) and sub-borate of soda, (borax,) and keep it in a fused state for thirty or forty minutes, then separate the two crucibles, and pour the metal in an ingot mould of the proper size, previously warmed and oiled. Most of the base metals will be dissipated during the process of fusion in the form of vapor, the lead escaping into the pores of the crucible. The bichloride of mercury (corrosive sublimate) is sometimes used instead of the nitrate of potassa, for the purpose of dissipating the base metals, and often with more certain and better results. If the gold cracks on being hammered or rolled, it should be melted again, and more nitrate of potassa, and sub-borate of soda thrown into it; but the inside of the crucible should be well rubbed with the latter, before the metal is put in. It is sometimes necessary to repeat this process several times, and if the gold still continues brittle, a little muriate of

* Chemistry of the Arts, vol. ii, p. 551.

ammonia (sal ammoniac) may be thrown into the crucible when the gold is in a fused state, and after the vapor ceases to escape, the metal may be poured into an ingot mould, warmed and oiled as before directed. This last method of treatment will make the gold tough, and prevent it from cracking under the hammer, or while being rolled, if it be, from time to time, properly annealed.

To separate platina from gold, it is necessary to dissolve the alloy in a mixture of nitric and muriatic acids, and afterwards to pour in a solution of muriate of ammonia, which will cause the former metal to be precipitated. The acid may then be poured into another vessel, and the gold precipitated by pouring a solution of sulphate of iron into it.

By the foregoing methods of refining gold, sufficiently accurate results will be obtained for all useful practical purposes in mechanical dentistry, and as this is the object at which the author aims, he does not deem it necessary to go into a minute detail of the various complex processes employed for separating the several metals occasionally found combined with the one under consideration. The variation of an eighth or a quarter of a carat in the fineness of the gold employed in connection with artificial teeth, is not a matter of much consequence.*

* The method of procedure pursued by Dr. Elliot for refining gold is as follows : He says, "The following implements are necessary for this purpose : a small draught furnace, a quantity of fine hard-wood coal, a clean crucible, with a sheet-iron cover, a light crucible tongs, an ingot mould made of soapstone, a little nitrate of potassa, carbonate of potassa, borax and oil. The fireplace of the furnace should be about ten inches in diameter, and eight or ten deep ; this should be connected by means of a pipe with the chimney, so that a powerful draught may be made to pass through the coal. A blast furnace is objectionable, for the reason that the bellows burns out the coal immediately under the crucible, and it is therefore constantly dropping down, which is not the case with the draught furnace ; besides, the draught furnace produces a more even fire, a quality equally indispensable.

"In preparing for a heat, the furnace should be filled about half full of coal, and after it is well ignited, it should be consolidated as much as practicable without choking the draught. The crucible containing the metal and a little borax may then be set on, and more coal placed around and over it, the door of the furnace closed, and the damper opened ; it should remain in this way until the gold is perfectly fused, the coal may then be removed from over the crucible, and a bit of nitrate of potassa dropped in, in quantity equal to the size of a pea to every ounce of

ALLOYING GOLD.

Gold, when in an unalloyed or pure state, as has been before stated, is too soft for a support for artificial teeth, consequently, it has been found necessary to combine with it some other metal, in order to harden it. Silver and copper are the alloys most frequently employed. Many dentists prefer the former, for the reason, as they erroneously suppose, that it does not increase the liability of gold to tarnish as much as the latter. But this opinion is neither sustained by facts nor experience. Gold, when alloyed with copper, unless reduced altogether too much for dental purposes, will resist the action of acids as effectually as when alloyed with silver, and the former renders it much harder than the lat-

gold, and the crucible immediately covered with a plate of iron; more coal may then be placed over and around the crucible, and the gold kept in a fused state at a high temperature, until the scoria ceases to pass off, which it will do in the course of five or six minutes. The ingot mould having been previously warmed, may be placed in a convenient position for pouring, and filled about half full of lamp oil. The iron cover may now be thrown off quickly, the crucible seized with the tongs, and at the same instant another small bit of nitrate of potassa should be thrown into it, and the gold rapidly, but carefully poured into the mould.

"The ingot always cools first at the edges, and shrinks away from the middle; on that account the mould should be a little concave on the sides, so that the shrinking will not reduce the ingot thinner in the centre than at the edges.

"Moulds of the best form will sometimes produce ingots of irregular thickness; such ingots should be brought to a uniform thickness under the hammer, using the common callipers as a gauge; if this be neglected, the plate will be found imperfect at those points where the ingot was thinnest. The plate should be annealed occasionally during the process of hammering and rolling, and should be reduced about one number in thickness each time it passes between the rolls. If any lead, tin or zinc be mixed with the gold, the nitrate of potassa must be used in much larger quantities, and in that case, it is better to let the button cool in the bottom of the crucible; then break the crucible and melt it in a clean one for pouring, using borax and nitrate of potassa in very small quantities for the last melt.

"In case the subject of assay be in the form of fillings or dust, a magnet should be passed through it so as to remove every particle of iron, and then, instead of melting it with borax, it should be melted first with *carbonate of potassa*, and afterwards with nitrate of potassa, in quantities proportioned to the necessities of the case as before directed; carbonate of potassa is the only flux that will bring all the small particles of metal into one mass; without it, a great portion of the gold will be found among the scoria, adhering to the sides of the crucible, in the form of small globules. The process of refining, answers equally as well for silver as gold."—*Am. Jour. Dent. Sci.*, vol. vii, pp. 71-2.

ter. Besides, it renders the gold susceptible of a higher and more beautiful finish. If, therefore, but one of these metals is used, copper may be regarded as preferable to silver, but two or three parts of the former, and one of the latter, constitutes a better alloy for gold, used as a basis for artificial teeth, than either, separately from the other.

The gold employed in mechanical dentistry by most practitioners, is altogether too impure for the purpose, it being not more than from fifteen to seventeen carats fine, and sometimes it is reduced even to fourteen. When not above these standards of fineness, it is discolored by the buccal secretions, and it imparts an exceedingly disagreeable taste to the mouth. The plate which is to serve as a basis for artificial teeth should never be reduced below twenty carats, and as that for the upper jaw does not require to be more than one-third or one-half as thick as that of the lower, the gold for the latter may be a little finer than that employed for the former, as it is necessary that it should be more malleable. The following standards of fineness may be regarded as the best that can be adopted for gold used in connection with artificial teeth.

Plate for the upper jaw, twenty carats; for the lower, twenty-one, and for clasps and wire for spiral springs, eighteen. In reducing perfectly pure, or twenty-four carat gold, to these standards, the following are the proper proportions of alloy to be employed:

1. For twenty carat gold: take 20 dwts. pure gold, 3 dwts. fine copper, and 1 dwt. silver.
2. For twenty-one carat gold: take 21 dwts. pure gold, 2 dwts. fine copper, and 1 dwt. silver.
3. For eighteen carat gold: take 18 dwts. pure gold, 5 dwts. best copper, and 1 dwt. silver.

The gold should be first melted in a clean crucible, and as soon as it has become thoroughly fused, the silver and then the copper may be thrown in with two or three small lumps of sub-borate of soda. After keeping the whole in a melted state for some five or ten minutes, it may be poured

into an ingot mould of the proper size, previously warmed and oiled. If the gold cracks during the process of hammering or rolling, it may be melted again, and a few small pieces of sub-borate of soda, with a little muriate of ammonia thrown in. In five or ten minutes, it may be recast into an ingot.

When scraps and filings are to be converted into plate, they should first be refined, afterwards properly alloyed. This may also be necessary with all gold the quality or fineness of which is not known, but with national coins having a known fixed standard, this will not be necessary, unless they are below twenty-one or twenty carats. When they are above these standards of fineness, a sufficient amount of alloy may be added to reduce them to the one required.

MANNER OF MAKING SPRINGS FOR THE SUPPORT OF ARTIFICIAL TEETH.

The springs most frequently employed, at the present day, for confining artificial teeth in the mouth, are made by

FIG. 161.

winding a small gold wire around a spindle, until a coil of sufficient length has been formed. The wire for this purpose should never be thicker than is absolutely necessary to give to the springs the requisite degree of power, and is formed by forcing a piece of gold, properly alloyed and previously forged into a small oblong shape, through a series

of progressively diminished holes in a steel plate, like the one represented in Fig. 161, until the requisite fineness is attained. For overcoming the adhesion of the particles of the metal, a machine called the draw-bench is required.

FIG. 162.

See Fig. 162. The jaws of the pincers which hold the extremity of the wire, for pulling it through the successively diminishing holes of the plate, are cut on the inside like a file. While the plate is confined at one end of the bench,

FIG. 163.

the pincers are attached to a band wound round a roller, turned by a crank at the other. After the wire has been

grasped, the crank should be slowly turned, but the motion should be steady, for if it proceeds irregularly, it will cause inequalities in the wire. To prevent the gold from becoming too hard and brittle, it should be annealed between the successive drawings.

The simplest method of winding the wire into a spiral spring, is to secure it between two blocks of wood, held between the jaws of a small bench-vice. The upper end of the wire is then grasped in connection with a small spindle or steel-wire, the size of a small knitting-needle, six or eight inches in length, by a hand-vice or sliding-tongs; the spindle resting on the blocks of wood is made to revolve by turning the hand-vice or sliding-tongs. By this movement the gold wire is wound firmly and closely round the steel rod or spindle. See Fig. 163.

But by means of the machine represented in Fig. 164, and invented by Dr. Howcott and Davidson, dentists, of Memphis, Tenn., the wire may be wound with much greater uniformity and accuracy. This is the most perfect contrivance ever employed for the purpose. It is simple in its construction, and the great superiority which it possesses

FIG. 164.

over the other means employed for winding wire, consists in the accuracy of its operation.

MANNER OF MAKING GOLD PLATE.

The gold after being melted in a clean crucible, well rubbed on the inside with borax, should be poured into an ingot mould of the proper length, width and thickness; then after it has become sufficiently cool, it may be placed on an anvil, and its thickness reduced to about an eighth of an inch, with a hammer of suitable weight. It should now be well annealed by being placed in the furnace, lightly covered with small pieces of charcoal and heated until every part of it becomes red. It may be necessary during the operation of hammering, to subject it once or twice to this process, to prevent the gold from cracking, and if, notwithstanding this precaution, it does crack, it should be again melted, and in addition to the borax, a little muriate of ammonia may be thrown into the crucible as soon as it becomes melted. It is then recast into an ingot, and forged without danger of again cracking unless cooled too suddenly. In this case it will be thicker at the sides than in the centre, and may become flawy in forging. This, therefore, should be guarded against as much as possible, by cooling gradually.

FIG. 165.

FIG. 166.

After the gold has been reduced to the thickness just mentioned, and well annealed, it may be placed between the rollers of the mill, previously so adjusted, as to be the same

FIG. 165. A sliding ingot mould. It may be made of iron or soap-stone.

FIG. 167.

distance apart at both ends, and not so near to each other as to require a great effort to force it between them. The rollers, however, should be brought a little nearer to each other every time the plate is passed between them, and during this process they should be kept well oiled, so that there may be as little friction as possible.

Rolling mills for gold are variously constructed. Some are very simple, while others are quite complex, having a great deal of machinery connected with them. The rollers also vary in length. For the gold plate used by dentists, they need not be more than three or three and a half inches long. A mill like the one represented in Fig. 166 will be found to answer all practical purposes. It is worked, as may be perceived, by two cranks, one to each roller, but fixed on opposite sides of the mill, so that two persons are required to turn them.

While the gold is being rolled, it should be frequently annealed.

The thickness of the plate may be determined by a gauge plate, like the one represented in Fig. 167. That which is to serve as a basis for artificial teeth for the upper jaw, may be reduced until it fits the gauge at 25 or 26; for the lower jaw, 21 or 22; for backings for the teeth, at 24; and plate for clasps, at 23. It is sometimes neces-

sary, however, to vary the thickness of the plate used for these several purposes; as for example, when the whole alveolar border and a portion of the roof of the mouth is to be covered, it may be a little thinner than when applied only to a small surface. When very wide clasps too, are employed, it is not necessary that the gold should be as thick as is required for narrow ones. But these are matters which the judgment of the dentist alone can properly determine, and consequently no rules can be laid down upon this subject, from which it will not sometimes be necessary to deviate.

The gauge plate represented above has only 26 numbers; some are made with from four to fourteen more.

MANNER OF MAKING GOLD SOLDER.

In making gold solder, the metals employed for the purpose, if not pure, should be refined separately. Unless this is done, it would be difficult to ascertain their relative purity, which should be known to insure the desired result. The gold is placed in a clean crucible with a little borax, and as soon as it has become perfectly melted, the silver, and afterwards the copper, is added. When all are melted, the alloy may be immediately poured into an ingot mould, previously warmed and oiled.

The process of hammering and rolling the solder is the same as that described for gold plate.

The solder employed for uniting the various parts of a piece of dental mechanism, should be sufficiently fine to prevent it from being easily acted on by the secretions of the mouth. Either of the following recipes will be found well adapted to the purpose:

FINE FLOWING GOLD SOLDER.

RECIPE, NO. 1.

2 dwts. 22 carat gold,
16 grs. fine silver,
12 grs. roset copper.

RECIPE, NO. 2.

1 dwt. 15 grs. 22 carat gold,
16 grs. fine silver,
12 grs. roset copper.

The following makes rather finer solder than either of the above, and although it requires a little stronger blast to melt it, it flows very freely.

FINE FLOWING GOLD SOLDER.

RECIPE, NO. 3.

6 dwts. pure gold,
2 dwts. roset copper,
1 dwt. fine silver.

By adding two or three grains of spelter, solder, finer than that made by either of the foregoing recipes, may be employed without any increase of heat. It will also have a finer gold color, but it is apt to impart to the piece a brassy taste, and for this reason the author rarely uses it. Several other recipes might be added, but the foregoing are sufficient.

CHAPTER SEVENTH.

WAX AND PLASTER OF PARIS IMPRESSIONS OF THE MOUTH, PLASTER MODELS—ALSO, METALLIC MODELS AND COUNTER-MODELS.

IN the construction of a dental substitute mounted on a base, it is necessary to obtain an exact model of the parts upon which it is to rest, and to which it is to be attached, but before this can be done, a perfect impression in wax, or some other soft and yielding substance, must be procured. The manner of obtaining this is as follows.

WAX IMPRESSIONS.

FIG. 168.

Fill a frame of suitable dimensions, like the one represented in Fig. 168, made of silver or tin, with white or yellow wax, softened in warm water or by a fire, until it is of the consistency of dough, or soft putty; then put it in the mouth with the wax facing the jaw to be supplied with artificial teeth, and press it carefully against it, covering the whole of the vacant space and the adjoining teeth as far back as it may be necessary to extend the plate. The pressure on the frame should be sufficiently great to imbed the teeth and the alveolar ridge completely in the wax. The frame

should be held steadily in the hand of the operator, pressing upon every part of it alike. The wax is pressed up against the gums on each side with the finger, so that an exact impression may be obtained of all the depressions and protuberances of the parts on which the plate is to rest, and of the remaining teeth. On the removal of the frame and wax from the mouth, the greatest precaution is necessary to prevent injuring or altering the shape of the impression.

FIG. 169.

Every dentist should be supplied with several of these frames, differing in size, so that he may never be at a loss for one of the right dimensions. When an impression of only one side of the mouth and the front part of the alveolar ridge is required, a frame like the one represented in Fig. 169 will be found most convenient, but when such are used, it is necessary to have one for each side of the jaw.

Dr. Elliot recommends that the wax-frame be "formed by being struck up between a model and counter-model, in the same way that a gum plate is fitted to the mouth."* Wax-holders, thus formed, would, doubtless, be more convenient than those just described, but, with care, an accurate impression, in most cases, can readily be obtained with either.

In several cases, however, since the publication of the second edition of this work, we have been compelled to construct a wax-holder in the manner as described by Dr. E., with which we readily succeeded in obtaining a perfect impression, after having previously made several unsuccessful attempts to procure them with the ordinary wax-holders.

After removing the impression from the mouth, oil should be applied to it with a camel's-hair pencil or brush, and a wire about three-fourths of an inch long, stuck into the

* American Journal of Dental Science, vol. v, p. 90.

centre of the bottom of each cavity made in the wax by the teeth next the vacant space, and those to which the clasps are to be applied, to prevent the liability of the plaster teeth from being broken.

FIG. 170.

The wax impression, prepared in this manner, will present the appearance exhibited in Fig. 170. It is scarcely necessary to add, that unless the impression is perfect, it will be impossible to fit a plate to the parts of the mouth to which it is to be applied with a sufficient degree of accuracy to be worn with impunity.

Dr. J. A. Cleaveland contrived a set of wax-holders, admirably adapted for taking impressions, both of the lower and upper jaw. Those for the upper jaw, encase the alveolar border, and cover the roof of the mouth more perfectly than the common wax-holder, possessing the advantages of the one recommended by Dr. Elliot, without subjecting the operator to the inconvenience and loss of time of making one for each individual case. By having three holders for the upper jaw, each varying in size from the other, one will be found to fit almost any case which may occur, with sufficient accuracy for all practical purposes. For the purpose of insuring a perfect impression in those cases where the alveolar border is very deep, the author has a hole cut through the centre of each, as seen in Fig. 171, to enable

him to press the wax up against the anterior part of the roof of the mouth with the finger.

For the lower jaw, Dr. Cleaveland employs two wax-holders—one for taking impressions where six or eight of the

FIG. 171.

FIG. 172.

front teeth are remaining, and the other for taking impressions of the alveolar border in which there are no teeth. Each has a joint in the centre, so that it can be made wider or narrower at pleasure, to suit the size of the jaw. Without the central joint or hinge, a greater number of holders are required, three of each kind, and each differing in size from the other, will afford sufficient variety to enable the operator to take an impression of almost any jaw.

FIG. 173.

In Fig. 172 is represented one of Dr. Cleaveland's wax-holders for taking an impression of the alveolar bor-

der without teeth, and without the central joint; and in Fig. 173, is seen an engraving of one designed for the procurement of an impression of a lower jaw in which six or eight of the front teeth are remaining.

There are many cases in which it is impossible to remove a wax impression from the mouth without injury. In such cases plaster of paris may be substituted. With this, a satisfactory result may always be obtained.*

PLASTER OF PARIS IMPRESSIONS.

Plaster of paris, gypsum or sulphate of lime, consists of 28 parts of lime; 40 of sulphuric acid, and 18 of water. When exposed to a heat of 400° Fahr. the water of the gypsum escapes. After being properly calcined and pulverized, if mixed with water to the consistence of thin batter or cream, it hardens in a few minutes, by a species of crystallization, and acquires great solidity. During the first part of the process of consolidation, it expands, by the absorption of the water, so as to fill the small depressions in any mould in which it may be poured.

But there is a great difference in the quality of plaster of paris. That used for taking impressions and models of the mouth should be of the best description, well calcined, finely pulverized, and passed through a sieve previously to being used.

In taking a plaster impression of the mouth, the first thing to be done, is to place a rim of wax, previously softened in warm water, or by a fire, around the rim of a wax-holder of the proper size, closing up the open ends, so that when applied, it will completely encase the alveolar ridge of the upper jaw, then fill it with a thin batter, made of calcined plaster of paris and water, and before it begins to concrete, put it into the mouth, and apply it to the upper

* The idea of taking impressions of the mouth with plaster of paris, originated, we believe, almost simultaneously with Drs. Westcott, Dunning, and Bridges.

alveolar border, and press it upwards, until a sufficiently deep and accurate impression is made of the ridge, remaining teeth if there are any, and anterior portion of the roof of the mouth. In doing this, it may be necessary to pass the fore-finger around on the outside and inside, pressing the plaster gently against the parts. An accurate impression having been obtained, it should remain in the mouth two or three minutes, or long enough for the plaster to harden, when it may be removed.* This, however, should be done with great care to prevent cracking or injuring the impression, and some difficulty is occasionally experienced in detaching it from the mouth, as the suction or atmospheric pressure is often so considerable, as to make it adhere with great tenacity. When this is the case, one side should be first gently depressed, and if it cannot be readily loosened at one point, another and another may be tried until some one is made to yield; when the whole may be easily removed.

A correct plaster impression having been obtained, the edges are smoothly trimmed, and after it has become perfectly dry, it is oiled or varnished before it is used for the procurement of a model.

The method of obtaining a transfer of the alveolar ridge, recommended by M. Desirabode, will always, with proper care, secure the most accurate and successful results. It consists, after having obtained a metallic model and counter-model, in striking up a lead plate, trimming it to the proper size, and adjusting it with the finger to the alveolar border, until it is made to fit every part with *perfect* accuracy. It is then carefully removed, and used instead of the original wax impression, for the procurement of a second plaster model. From this last, new metallic castings are obtained, and from which a perfect atmospheric pressure or suction plate may be procured.†

* The solidification of the plaster will be hastened by adding a little salt or sulphate of potash.

† Vide *Nouveaux Elements Complets de la Science et de l'art. Du Dentiste*, t. 2, pp. 636-7.

PLASTER MODELS.

The impression, whether taken in wax or plaster, is first oiled, then filled with a thin paste or batter made of the best calcined plaster of paris and water. This is at first poured in while it is quite thin, and with great care, until the impressions made by the teeth, if there are any remaining in the jaw, are filled; after which, the batter may be allowed to thicken a little before the remainder of the impression is filled; it is then poured on until the plaster is raised an inch or an inch and a half above the impression.

FIG. 174.

After the plaster has sufficiently hardened, it may be trimmed, and after softening the wax in warm water, or by a fire, it is removed from it. The same impression can sometimes be used a second or third time, but lest the shape of it should be altered in the removal of the model, a duplicate impression may be taken. The plaster model may be shaped with a knife, until it presents an appearance something like that represented in Fig. 174, that a metallic cast obtained from it may be easily withdrawn from an impression of the same or a similar material.

The model, after having been thus trimmed, should have several coats of shellac or sandarach varnish applied to it with a small brush, to give it a smooth, hard and polished surface. This will prevent it from wearing away by use, and render it more pleasant to the touch of the hand. The sandarach varnish is preferable to the shellac, as it is more transparent, and, consequently, does not color the plaster. It may be made in the following manner: take sandarach, $\frac{3}{4}$ v, elemi, $\frac{3}{4}$ i, digest in one quart of alcohol, moderately warm, until dissolved, then add Venice turpentine, $\frac{3}{4}$ ij. This is, perhaps, as good a varnish as can be used for plaster models. It is easily prepared, but in warming the alcohol, some care is necessary to prevent it from taking fire.

The sandarach should be of the most transparent quality, and washed in water before being put into the alcohol.

FIG. 175.

For striking up a plate with the outer edge turned up, a groove, about an eighth of an inch deep is formed around the outside of the plaster model, where it is designed that the edge of the base shall terminate on the alveolar border, by the application of yellow wax, previously softened, which is afterwards cut away with a knife until a groove of the

proper shape is formed. A plaster model of the upper jaw thus prepared, is represented in Fig. 175. A plate swaged with dies, from such a model, is only used for mounting gum or block teeth. A dental substitute with a base of this kind is stronger than a simple plate and is susceptible of a more beautiful finish.

For a lower set of block teeth, the edge of the plate may be turned up all the way round. But rimming teeth, as it

is termed in mechanical dentistry, which consists in soldering a narrow strip of gold to the outer edge of the plate in such a manner as to cover the outer surface of the extremities of the teeth or edge of the blocks near the base, is on some accounts, preferable to a plate with a turned edge. The manner of doing this, will be described in the chapter on porcelain block tooth.

FIG. 176.

It sometimes happens, when the alveolar ridge is very deep, that the lower edge of the arch inclines outwardly so much as to make the span of it here considerably greater than it is a quarter or half an inch higher up. In this case, if sand be used in procuring a metallic model, it is difficult to remove the plaster without injuring the impression made in the sand. To obviate which, the plaster model is so constructed as to consist of three pieces, or sections, in the manner as represented in Fig. 176,* which however, only shows two sections of the model. After the three are put together, in the manner as shown in Fig. 177, it may be pressed in the sand until a good impression is made, and afterwards

* Dr. G. E. Hawes, of New York has invented a moulding flask, by the use of which, the plaster model may be taken from the sand without injuring the impression. A description of this will be given when we come to treat of the manner of procuring a metallic model. When it becomes necessary to obtain metallic castings for the construction of appliances for remedying irregularity of the teeth, this flask, is often very valuable.

removed separately. Dr. Westcott, we believe, was the first to introduce the use of this description of plaster model, which may be procured by first filling the wax impression with the plaster as in the manner before described ; this is then removed, and about one-third from each side trimmed off, leaving the lower surface wider than the upper. This

FIG. 177.

done, it is replaced in the impression, and filled up on each side with plaster as in the first instance ; after the last has consolidated, the model is properly trimmed, and when it has become perfectly dry, varnished.

A METALLIC MODEL AND COUNTER-MODEL.

Various methods have been adopted for procuring metallic models and counter-models, but the two following are all which the author deems it necessary to describe. One of these consists in pouring melted metal in an impression made in sand with the plaster model. By this means a metallic model is procured, and the female or counter-model obtained either by immersing this in, or pouring melted metal on it. The other consists in making the counter-model first, by either immersing the plaster model in, or pouring melted metal on it, and afterwards obtaining the male model by pouring melted metal in this.

When they are to be obtained by the first method, a box is required about six inches square and three or four inches deep. This is filled with fine sand, such as is employed in brass and iron founderies. After this has been slightly dampened, the plaster model is pressed in it to the depth of an inch or an inch and a half, leaving a portion of it unimbedded, that, at the proper time, it may be readily removed. The sand is thoroughly packed on every side of the plaster model, which, after this has been done, is gently tapped several times with some light instrument or hammer, for the purpose of starting or detaching it a little from the matrix, and then carefully removed. If the model be composed of three pieces, the middle section is first removed, and afterwards the two others.

A shallow furrow or groove, of about an inch in length, is now formed in the sand, on one side of the mould leading to it, and both the furrow and mould are then encircled with a rim of sheet iron of about three inches in diameter, and an inch and a quarter in width. If, in the meantime, any particles of sand have fallen into the mould, they may be removed by blowing gently into it.

The mould being now prepared, the metal to be employed for the casting may be put in a tolerable thick wrought iron ladle, and melted either in a common fire or furnace. If brass is used, the latter will be required to melt it, but if zinc, block tin or lead, a common fire will afford sufficient heat. After the metal has become thoroughly melted, it is poured on the inside of the ring into the furrow formed in the sand, when it will immediately flow into the mould. It is necessary to convey the melted metal into the mould in this way to prevent the liability to injury which it might sustain by pouring directly into it.

If zinc or block-tin is used, a sufficient quantity may be melted to fill nearly the whole of the ring, but if brass is employed, it will only be necessary to fill the mould in the sand. It is only when a very thick plate is to be struck up or an encasement to be placed on one or more of the natu-

ral teeth that brass is required. For all ordinary purposes, either of the two first metals will answer. The first is usually employed for the male, and the second for the female model.

But if the plaster model is used in one piece, and the shape of it is such that it cannot be drawn without dragging more or less of the sand with it, the moulding flask of Dr. G. E. Hawes, represented in Figs. 178, 179 and 180, may be employed.

FIG. 178.

FIG. 179.

FIG. 180.

The manner of using it is thus described by Dr. C. C. Allen: "If the model be considerably smaller than the space between the flanges projecting in towards it, small slips of paper may be placed in the joint extending to

the sides of the model, to part the sand when opening the flask, for the removal of the pattern. The sand may now be transferred around the pattern up to the most prominent part of the gum, and it should be finished smoothly around it, slightly descending towards the model, so as to form a thick edge of sand for the more perfect parting of the flask. The sand and face of the model must now be covered with dry pulverized charcoal, sifted evenly over the whole surface. When this is done, the upper section of the flask is

FIG. 178. The lower section of the flask, slightly opened to show joints. FIG. 179, the upper section. FIG. 180, the lower section closed, and confined by a pin, with the plaster model placed in it.

placed over the lower, and carefully filled with sand. It is then raised from the lower one, which may then be parted by removing the long pin, and the model gently taken away. When closed, and the two put together again and inverted, it is ready to receive the melted metal."*

After the casting has cooled, it may be removed, or rather turned over, so that the part presenting a transcript of the plaster *model* shall be upwards, while the remainder is buried in the sand. The casting thus placed, is encircled with the ring first employed, and if the casting be made of block-tin, it is covered with a thin coating of whiting, mixed with water, until it is of the consistence of cream. This may be put on with a camel's-hair pencil, and after it has become perfectly dry, a sufficient quantity to fill the ring, of block-tin or lead, may be melted in the ladle as before directed, and when its temperature has become so much reduced as to not to char or even discolor white paper, it may be immediately poured into it.

If the last metal be poured into the ring while it is at a higher temperature, or if the precaution of covering the exposed part of the first casting with whiting, is not used, the two will be liable to unite. Even when zinc is used for the first casting, there is danger of fusing it if the metal poured on be too hot. When the last metal used requires as high or nearly as high a heat to melt it as the first, an accident of this sort is still more liable to occur, unless great care is taken to prevent it.

The gas generated by the decomposition of the water in the sand, sometimes collects under, or diffuses itself through the metal, and renders the casting more or less imperfect. This, in most instances, may be prevented by pouring the metal slowly, or by making a small opening through it with a wire for its escape, before it has congealed.

After the last metal has cooled, the castings may be separated, and if perfect, they are ready for use.

By the second method of procedure, the use of sand is

* New York Dental Recorder.

wholly dispensed with, and this, for the reason, that smoother castings may be secured, is, in most cases, preferable to the first. It consists in pouring melted lead into a sheet or cast iron cup or box, of about three and a half or four inches in diameter, and three inches deep, until it is half full, and immediately immersing so much of the plaster model in it as represents the shape of the alveolar ridge and remaining teeth, if the latter be left on the model, and holding it there until the lead congeals. It is then removed, and the whole upper surface of the lead, including that of the mould made in it with the plaster-model, covered with a thin coating of whiting in the manner as before directed. After this has become perfectly dry, melted block-tin, at a temperature so low that it will not char, or even discolor white paper when dipped and held in it, may be poured on, until the cup or box is filled. When cold, the castings may be removed from the iron cup or box, and separated. This done, they are ready for use.

When a metallic model and counter-model are procured in the manner as last described, the plaster model should not be varnished, and as the one immersed in the melted metal is generally broken in removing it, a duplicate, varnished as before directed, should be obtained.

When it is necessary to have brass or zinc castings, they are made in sand, as first described.

Finally, by cutting about three-fourths of the crowns of the teeth from the plaster model, before using it for obtaining metallic casts, the plate may be fitted more easily and perfectly to the teeth, around which clasps are to be placed, than can be done when they remain on the plaster model, for, in the former case, it need not be cut to fit the teeth until it has been swaged, while in the latter, this must be done first, and, consequently, in striking it up, it will be drawn to a greater or less distance from them.

CHAPTER EIGHTH.

SWAGING A PLATE AND SOLDERING CLASPS TO IT.

A MODEL and counter-model having been obtained, a piece of sheet-lead is adapted to the alveolor ridge, and the dimensions of the plate marked upon it with a pointed instrument. The pattern thus marked is cut out, laid upon a piece of gold plate of the right thickness, and its size and shape marked upon it. With a pair of strong shears or snips, (see Fig. 181,) the portion of plate thus marked is cut out. It may

FIG. 181.

now be annealed, and then partially adjusted and fitted to the model with a hammer and pair of plate-forceps; again annealed, and afterwards swaged between the metallic model and counter-model. It may be necessary to repeat this operation several times, annealing the plate each time, before a perfect adaptation can be obtained. This done, it should be filed to the exact size required, and made to fit the teeth to which it is to be clasped with perfect accuracy.

When block-tin or lead models or counter-models are used as swages for the plate, any portion of these metals which may adhere to it, should be removed before annealing, as the fusions of such portions upon its surface, by this process, will render the gold brittle, and, in some degree, destroy

its ductility. But the liability of the tin or lead to adhere to the gold may be measurably prevented by oiling the plate before it is struck up.

After fitting it to the model, it is applied to the mouth, for the purpose of ascertaining if the impression from which the model was procured is correct. It sometimes happens that this is imperfect; in which case, a new one will have to be taken, and the whole process of procuring plaster and metallic models and counter-models again gone through with, and hence the propriety of the precaution of trying it in the mouth before the clasps and teeth are attached. To be worn with comfort, and at the same time to subserve any valuable purpose, it is important that the plate fit perfectly all the inequalities of the parts to which it is applied. When an unbroken series of several teeth are to be supplied, it seldom happens that much difficulty is experienced in fitting the plate, but when the loss of six or eight teeth, from different parts of the dental arch, are to be replaced, with substitutes attached to a single plate, a perfect adaptation to the various inequalities of all the parts cannot always be so easily secured.

With regard to the width of the plate, and the peculiar form and shape that should be given to it in different cases, the reader will be able to form a pretty correct idea, from the illustrations given in a subsequent chapter.

FITTING THE CLASPS.

The plate being fitted, it is applied to the plaster model, and the clasps adapted to teeth—one on each side of the mouth, and here it may be proper to repeat, that the gold employed for this purpose should be about one-third or one-half thicker than the plate, and when practicable, nearly as wide as the crowns of the teeth are long, and carefully and accurately fitted. This is necessary to secure to the piece the greatest possible amount of stability, and to prevent the clasps from acting as retractors, or exercising an undue

force upon the teeth. These are precautions which should never be overlooked, for, if the clasps act unequally upon the teeth, inflammation of the alveolo-dental membrane will be set up, followed by wasting of their sockets, and ultimately loss of the teeth.

When accurately fitted, they may be attached to the plate by means of a small piece of wax, or cement composed of two parts wax, and one of resin, previously softened, and applied to the plate and to the inner or palatine side of each clasp. The plate and clasps thus united, are carefully removed from the plaster model and laid with the convex side downward on a piece of paper. A paste or batter of plaster of paris is now poured on the upper side of the plate and clasps to the thickness of half an inch. After this has become dry, the piece may be taken from the paper, turned over, placed on charcoal and the wax softened and removed.

This is the usual way of fitting the clasps to the plate and preparing the piece for soldering, but when the teeth in the mouth to which these fastenings are to be applied, deviate from a vertical position, they may be fitted in the mouth, instead of to the teeth on the plaster model, and attached to the plate, as just directed. In this case only one can be attached at a time, and after this has been soldered, it should be opened, the piece placed back in the mouth, and the other made fast to the plate. The greatest care too will be necessary to prevent moving or altering the position of the clasp in taking the piece from the mouth.

Dr. Fogle adopts a different method for securing accurate adaptation of the clasps.* These are first fitted to the plaster model, leaving the ends straight. A narrow strip of plate, about five-eighths of an inch in length, is employed as the temporary fastening. One end is soldered to the lingual surface of the clasp, the plate and clasp are now both placed on the model, and the other end fitted and soldered to the plate, forming a sort of semicircle or bow. Fig. 182

* Amer. Jour. and Lib. Dent. Sci., vol. 10, p. 35,

represents the plaster model, with the plate, clasp and temporary fastenings. In Fig. 183 is seen the plate, clasps and fastenings without the model.

FIG. 182.

FIG. 183.

The clasps are now only adjusted to the model, and however accurately they may have been adapted to this, it will be found on applying the plate to the mouth, that they will not fit the teeth there, but after properly adjusting them, the temporary fastenings hold them in the exact position in which they are placed while the piece is removed. This done, it may be placed on a piece of paper or charcoal, the concave side of the plate upwards, a batter of plaster applied, and the other steps connected with the process of permanent soldering gone through with.

In speaking of this method of applying clasps, Dr. Cushman says,* “In very difficult cases of adjustment as where the clasp-teeth stand *leaning*—where you have to fasten to the second or third molars, it will be found still more advantageous to pursue this plan, viz. after soldering one end of the strip to the clasp, and having bent the other to touch the plate when on the model, put both in their proper place in the mouth; then with a sharp pointed instrument, indicate the point where the bow touches the plate, place them on the model again, adjust the end of the bow to the point marked, confine it there and solder fast.”

* American Journal of Dental Science, No. 1, vol. 10.

Dr. Cushman says further, that he considers this method of adjusting clasps so valuable that he never ventures to set clasps permanently in the simplest case by the model.*

Mr. Noble, a student of the Baltimore College of Dental Surgery during the session of 1849-'50, suggests another method which is thus described by Dr. Austen :

“Let the clasp bind upon the tooth only with sufficient firmness to keep it in its proper place. Then mix a small quantity of plaster from a lot which, by previous trial, you find requires from six to ten minutes to set ; put it upon a piece of paper or sheet lead about an inch square, and just before it begins to harden, introduce it into the mouth upon the forefinger, pressing it into gentle contact with a portion of the plate and about one-half of the clasp. It must be held there for from three to six minutes, until it is sufficiently hard to break with a sharp fracture ; this point you can determine by examining the plaster left in your bowl. The plaster must then be withdrawn. Sometimes plate, clasp and plaster will be brought away together ; or the plaster and clasp together, leaving the plate ; or the plaster will separate, leaving both clasp and plate in the mouth. Should the plaster by any accident break, it can readily be united at the point of the fracture, without in the least altering its shape—one great advantage over wax. If the plaster adheres to the plate on withdrawal from the mouth, it must then be carefully detached, the plate replaced, and the same process repeated for the second clasp.

“Several precautions are necessary. If the clasp bind too tightly around the tooth, its ends will, when removed, spring together, and thus it will not exactly fill the original impression made in the plaster. If the part of the clasp which you design to cover with plaster be so regular in shape as to make its adjustment, when out of the mouth, uncertain, mark it with a file or by a small point of solder ; this will be copied in the plaster, and remove all doubt as to its defi-

* The cuts represented in Figs. 182 and 183, are from a model, with a plate, clasps and temporary fastenings furnished the author by Dr. Cushman.

nite position. If the plaster be extended over some part of the edge of the plate, it will, in the absence of any marked irregularities of surface, give a better guide for its re-adaptation. Lastly, if the plaster cover too much of the clasp-tooth, it will be more liable to break on being withdrawn.

“Take now the clasps, place them each in their separate impressions in the pieces of plaster, securing them if necessary by a small piece of softened wax. Place one end of your plate in its corresponding bed in one of the plaster pieces. If proper care has been used, both clasp and plate will fit into the plaster with unerring accuracy, and of course hold the precise relation as when in the mouth. While in this position, cover the clasp and the part of the plate on its surface with fresh plaster or plaster of paris and sand—and when this has hardened, remove the first plaster—just as in other cases you would remove the wax—preparatory to soldering.”

The author has not had any experience in either of the two last described methods, as he has always, since he has been acquainted with them, been able to secure an accurate adaptation of clasps by a simpler and less tedious process. Cases do sometimes occur, however, in which they may be resorted to with advantage.

SOLDERING CLASPS TO A PLATE.

The work having been placed upon a piece of charcoal, six or eight inches square, is made fast either with clamps, iron pins, or a paste of plaster of paris. The edge of the plate and clasps along the line of connection, are covered with a mixture of sub-borate of soda (borax) and water, of the consistence of thin cream, prepared by grinding the borax in clean soft water, on a piece of glass having a ground surface of from four to six inches in diameter, or, a piece of slate of the same size, until the mixture attains the above mentioned consistence. Thus prepared, it is applied with a camel's-hair pencil; after which several small pieces of

solder made from recipe No. 1 or 3, are placed along the line of connection between the clasps and plate.

The piece is now prepared for soldering, and it is hardly necessary to observe, that this process consists in uniting the clasps and plate by melting upon each, a more fusible metal, (the solder,) which serves, by chemical attraction and cohesive force, to unite or bind the pieces together. Thus, gold alloyed with silver and copper, melts more easily than the first named metal, and having an affinity for it, constitutes a proper uniting medium. The surfaces, however, of the pieces to be united, should be bright and smooth, to ensure a uniform effect of the solder upon them.

A number of ingenious contrivances have been invented for applying the heat.

FIG. 184.

The self-acting blow-pipe invented by Dr. Jahial Parmly, of New York, is one of the best and most convenient apparatuses for soldering which the author has seen. There is also a small furnace accompanying it, which is very useful

FIG. 184, *a a* Side of case; *b* Top of case thrown back; *c* Front of case united by hinge at bottom, and shown in a horizontal position; *d d* An oblong fluid vessel for reception of alcohol; *e* Vent to vessel *d d*, for introduction of fluid; *f* Burner introduced in groove of vessel *d d*; *g g* Movable extinguisher to burner *f*, and not for working the same. *h* Horizontal plate of tin for sustaining copper globe in place;

for heating up a piece preparatory to soldering, also, for melting metal for casts, and even gold. The apparatus is arranged in a small portable japanned tin case, which may be opened and closed at pleasure, as may be seen from the representation given in Fig. 184.

Dr. W. H. Elliot has added a very ingenious improvement to the self-acting-blow-pipe. We copy the following description and drawing, furnished by the author :

“This ingenious contrivance, useful as it may be to the dental artist, in its simple form, is far short of what it may be rendered, simply by supplying it with a larger quantity of the supporting principle of combustion.

“The fact, that the centre of the flame of the self-acting-blow-pipe, contains no oxygen, it is well known to every enlightened dentist, and may be proven by placing a rod of polished metal in the flame for a few seconds, in which case it will be seen that the surface of that portion of the rod occupying the centre of the flame does not unite with oxygen, however great the degree of heat may be; but if a jet of atmospheric air be thrown into the flame upon the rod, it will oxidize as readily as if heated by any other means. This little ex-

i Copper globe; *jj* An oblong vessel for the reception of alcohol; *k* Vent to vessel *jj*, for feeding same with fluid; *l* Burner extending from fluid in *jj*; *m* Extinguisher to burner *l*; *n* Syphon extending from fluid in vessel *jj*, to near the bottom of globe *i*; *o* Stop-cock to syphon; *p* Blow-pipe from top of globe *i*; *q* A small copper trough for retaining condensed vapor that escapes from blow-pipe.

The manner of working Dr. Parmly's self-acting-blow-pipe is very simple. The two vessels *d d* and *j j*, being filled with alcohol, the stop-cock *o* is closed; the mouth is then applied to the end of the blow-pipe *p* and the atmospheric air exhausted from the globe; when the stop-cock is turned, the alcohol in vessel *j* will rush through the syphon and fill the globe, should the air continue to be exhausted. For all practical purposes, the globe should be only partially filled, and the stop-cock turned so as to close the syphon. The burner *f* should be ignited, and in about five minutes, alcoholic vapor will be seen to rush out from blow-pipe *p*, when the burner *l* should be ignited. The volume of flame can be governed by the extinguishers *g* and *m*.

When the lamp is used for melting metal for castings, the metal should be placed in an iron ladle, and this latter in the furnace previously filled with charcoal, and placed in a proper position, as represented in Fig. 181, for the flame of the lamp to be thrown into it against the coal. When it is desired to melt gold, a crucible should be used instead of the iron ladle.

periment, proves not only the want of oxygen in the flame, but it leads to a very important conclusion, that without

FIG. 185.

FIG. 185. *a a* Air-pipe leading from the bellows to the lamp; *b* Vapor-pipe; *c c c* A round bellows, 10 inches in diameter; *d* A rod attached to the upper movable head of the bellows, and passing through cross-piece *e*, which serves to keep the head in a horizontal position; *f* A rod attached in a similar manner to the lower movable head of the bellows and passing down through the table; *g* A stirrup attached at the upper end to shaft *h h*; *i* support for shaft *h h*, by means of an arm projecting backwards from shaft *h h*, and attached to the lower end of rod *f*, the force is communicated from the foot of the artist to the bellows.

oxygen, the burning of the vapor must be gradual and imperfect. In consideration of this fact, the writer was led to make another experiment, that of producing a more perfect combustion, by throwing into the flame one of its supporters. This may be done in several ways, but the simplest and most convenient is atmospheric air, thrown in by means of a bellows. For this purpose, the exhalations of the lungs will not do as well, inasmuch as they not only contain less oxygen, but also contain a large portion of carbonic acid, which neutralizes so much of the remaining oxygen as to render it unfit for the support of combustion.

"The air-pipe must pass along by the vapor-pipe, and discharge about an inch and a half beyond it in the very centre of the flame, and in precisely the same direction. The calibre of the air-pipe at its apex, must be equal to that of the vapor-pipe; it must be made as small as possible without being enlarged at the end, as any enlargement there would derange the vapor flame; it must also be constructed of platina, as that is the only metal that will resist for any length of time, the heat of the burning vapor.

"The air-pipe appears to throw out a pale blue flame, about two inches in length, small and pointed. At the very point of this flame, the oxygen being all consumed, the greatest amount of heat is produced, and fusion of the solder takes place without oxydation; but within the blue flame, or far from it, where oxygen preponderates, oxydation of the solder goes on rapidly.

"The necessary weight to be given to the bellows, can only be determined by experiment, as it depends entirely upon the force of the rest of the instrument.

"The extra heat gained by the introduction of the air-pipe, is nearly all concentrated at the apex of the blue flame, which may be brought to bear upon the point, to be soldered, while the vapor flame keeps the whole work in a state of readiness."

Dr. R. Somerby has invented a furnace and blow-pipe, which every dentist would find exceedingly convenient and

useful in his mechanical workshop ; especially as it subserves a number of very valuable purposes.

FIG. 186.

FIG. 186. *a* A perspective of Dr. R. Somerby's concentrated blow-pipe and furnace; *b* The lamp; *c* Lamp stand; *d* Blow-pipe; *e* Cock, to cut off the air from blow-pipe; *f* Slide to raise or lower the lamp; *g* Top of table; *h* Cover to the fur-

The process of soldering is rendered more easy by this blow-pipe than by the usual method, and is, therefore, to those of the profession who are stationary, and occupy themselves much in mechanical dentistry, invaluable. The furnace attached to it answers all the purposes of melting gold, solder, and the metal employed for casts. The frame is made of iron, and so constructed and arranged as to occupy but little room. The smoke from the furnace is carried off by means of a stove-pipe—the lower piece of which, being so arranged that it may be raised and lowered at pleasure, and of a conical shape, so as to cover the whole of the opening into the furnace. When the furnace is used, this is raised, and let down when it is not needed. As useful as is this apparatus to the dentist, it is equally valuable to the chemist and mineralogist, or for any purpose requiring a steady blast from the blow-pipe or heat from a furnace.

The most common method, however, of soldering, is with an ordinary spirit or oil lamp and simple blow-pipe, but by either, considerable practice is necessary to accomplish the process with ease, and the perfection of finish, necessary to be put on a piece of dental mechanism, depends, in a great

FIG. 187.

measure, upon the manner in which this part of the operation is performed.

The lamp should hold at least a pint, and have a spout three or four inches long and about three-fourths of an inch in diameter. The appearance of such a lamp is exhibited in Fig. 187.

The blow-pipe should be from fifteen to eighteen inches

long, have a tolerably large orifice, and the end to be taken into the mouth should either be gilded or plated with silver. It is curved in the manner represented in Fig. 188.

FIG. 188.

When a spirit lamp is used, and the author thinks it preferable to oil, the wick should be large enough to fill the spout, to prevent the flame from extending back into the body of the lamp and causing an explosion, an accident very apt to happen when this precaution is not observed. The coal containing the work to be soldered, may be either held in the hand, or in a copper or sheet iron cup having a wooden handle. The flame of the lamp is first thrown upon the plaster, and kept there until its temperature is raised to a red heat, then directed upon the part to be soldered until it is heated to nearly a white heat, when it is brought to a smaller focus, and kept steadily upon the part where it is desired that the solder should take effect. When this melts and spreads itself along the line of connection between the clasp and plate, the point of flame is directed upon any other part or parts to be soldered.

If the flame be continued too long, there will be danger of melting the plate, and by an improper application of heat, the solder may be partially melted and run together, forming small globules. But a little practice will enable the student to determine the quantity of heat required and the length of time it should be continued. If the solder, after it has melted, flows in a wrong direction, the flame of the lamp is immediately concentrated upon the point where it should take effect, when it will at once be brought to it.

The plaster, after the piece has cooled sufficiently, is

removed, and the piece put in a mixture of equal parts of sulphuric acid and water, where it should remain long enough for the borax, which will be found adhering to the plate to be dissolved, and for cleansing the gold. But a few minutes, however, will be required for this.

The crystallized borax being removed, the solder, if rough, is filed smooth and rubbed with scotch-stone, before arranging and adjusting the teeth.

CHAPTER NINTH.

MANNER OF OBTAINING AN ANTAGONIZING MODEL.

IF the model is required for antagonizing only part of an upper denture—there being natural teeth in the lower jaw that antagonize with those which remain in the upper—it may be obtained in the following manner.

FIG. 189.

After having made the surface of the solder, uniting the plate and clasps, smooth with suitable scorpers, (scrapers,) and files, the plate should be placed in the mouth, and, if a series of artificial teeth are to be attached to it, a rim of softened bees-wax is placed on it; the patient is then requested to close his jaws *naturally*, imbedding the teeth of the lower jaw in it. While the mouth is thus closed, the wax on the outside of the teeth and alveolar ridge is pressed closely against them. This done, the patient may open his mouth, then the plate and wax impression are carefully removed and placed on a piece of paper, with the plate upwards. The upper side of the plate is now smeared with

olive oil, and filled with a thin paste made of plaster of paris. As soon as the plaster has become sufficiently thick, it may be applied until it is raised half an inch above the plate, and extended back of it on the paper an inch and a half or two inches. As soon as the plaster has set, it may be neatly trimmed around the edges, and on the lower surface behind the plate and wax, a deep crucial groove is cut, or several conical depressions, three-eighths of an inch deep, excavated, to serve as moulds for the formation of corresponding ridges or protuberances on the model with which this is to antagonize. The grooves or depressions thus formed, as well as the impression made in the wax by the teeth of the lower jaw, after the plaster has become dry, is oiled, and filled with a thin paste of plaster, and as soon as the latter has acquired sufficient consistence, it is poured on until this side is raised to a thickness equal to that of the side first filled.

By this simple contrivance, an exact representation of the manner in which the jaws meet, is obtained, and the most accurate and convenient antagonizing model procured that can possibly be made, and provided with this, the dentist is prepared to select, arrange and antagonize the teeth.

After the plaster has set, it may be trimmed as before directed. When it has become perfectly dry, the two pieces may be separated, and the wax and plate carefully removed. The model is now varnished, and when put together will present the appearance exhibited in Fig. 189.

When the model is designed for antagonizing a complete upper denture, a piece of wood, equal in width to the length required for the artificial teeth may be passed through the wax after it has been arranged to the plate at a point corresponding with, and in the direction of, the median line. The plate may then be placed in the mouth, and the patient directed to close his jaw *naturally*, until the teeth of the lower come in contact with the wood. The mouth may now be opened, and the plate and wax impression of the lower teeth removed. This done, the plaster model may be made in the

manner as before directed, and, when completed, it will present the appearance represented in Fig. 190.

FIG. 190.

An antagonizing model may also be made by adjusting a rim of wax to the plate corresponding in width to the length proposed for the artificial teeth, and cut away until all the teeth in the lower jaw touch it at the same instant. This done, the plaster is applied as before directed.

FIG. 191.

In making an antagonizing model for a complete denture, or double set of artificial teeth, the following is the usual method of procedure. After having fitted accurately both plates, a rim of soft bees-wax is placed between their con-

vex surfaces, of about an inch and a quarter in width. A piece of soft wood, exactly corresponding in width, to the length it is designed that both the upper and lower central incisors should have, is passed through the wax between the plates, at the median line. The whole is now placed in the mouth of the patient, and each plate accurately adjusted to the alveolar border. The patient is now directed to close his jaw naturally until the plates are brought in contact with the edges of the interposed piece of wood. This done, the whole may be removed from the mouth, the plates oiled, and a plaster model obtained in the manner as before described. See Fig. 191.

Another method of making an antagonizing model consists in placing a rim of wax on each plate, each corresponding in width to the length respectively designed for the teeth. The two plates are put in the mouth, the lower first, and then the upper. The jaws are now carefully closed; and if the rims of wax touch at any one point sooner than another, the plates are removed, the wax trimmed, and this operation repeated until the two rims of wax meet all the way round, at the same instant, and are exactly of the right

FIG. 192.

width. This done, the wax is trimmed on the outside, until the proper contour is given to the cheeks and lips. The

median line is now marked, the plates removed from the mouth, and the plaster antagonizing model made.

Dr. Thomas W. Evans has invented a very simple instrument, by means of which the extension of the plaster back of the plates and wax is rendered unnecessary. With an antagonizing model made in this instrument, the bite may be changed at pleasure, by increasing or diminishing the length of the rod between the frame work supporting the upper and lower parts of the model. The instrument is represented in Fig. 192.

FIG. 193.

In making an antagonizing model with this instrument, the following is the method of procedure pursued by the author. Supposing the model to be for an upper set of teeth, a rim of wax is placed upon the plate, and all the preparatory steps gone through, as already described. The concave part of the plate is oiled and filled with a batter of plaster; the upper part of the frame work of the instrument A A is placed on it, more plaster is then added until this is completely covered. When the plaster has set, it is turned over, so that the wax impression of the lower teeth and jaw is upwards; this is then filled with a batter of plaster, and the lower part of the frame-work of the instrument turning on the hinge-rod C is placed on it, the screw being loosened

so that the rod may not keep the jaws too wide apart. More plaster is added until the lower jaw of the instrument B B is imbedded in it. This done, the rod is moved until it presses against it behind the plaster, when it is made fast with the screw.

After the plaster has become hard, the jaws of the instrument are opened, the wax warmed and removed. The model will now present the appearance represented in Fig. 193. If it is found that longer or shorter teeth are required than is indicated by the model, the width of the bite may be increased or diminished, by increasing the length of the rod between the two jaws of the instrument.

CHAPTER TENTH.

ARRANGING, FITTING, ANTAGONIZING, AND ATTACHING PORCELAIN TEETH TO A PLATE—FINISHING AND AP- PLYING THE PIECE.

WHERE a vacuity, requiring only one or even five or six teeth, is to be filled, it is important that the artificial correspond in shade and color with the natural organs, for in proportion as they are whiter or darker, will the contrast be striking. But of the two, it is better that they should be a little darker than any whiter. Their outer configuration should resemble, too, the shape of those which have been lost.

As they are selected, they may be arranged on the plate, and retained in place by a piece of wax placed on it behind them. If they do not fit closely to the plate and gums, they may be ground on an emery or corundum wheel or small grindstone, until they do, and be so arranged as to meet the teeth with which they are intended to antagonize, at the same instant the natural teeth, that have antagonists, come together. The antagonizing models will enable the dentist to do this with the most perfect accuracy.

In arranging an entire set for the upper, or for both jaws, the teeth are so adjusted that the inner or palatine tubercles of the upper strike the depressions in the lower, before the outer tubercles come together. This precaution is necessary, in antagonizing single as well as block teeth. If the outer tubercles strike first, the pressure there will spring and loosen the plate. A small space, too, should be left between the last tooth of the upper and of the lower jaw.

It being necessary to cut away a considerable portion of a tooth in order to make it fit accurately to the plate, a number of corundum wheels, or small grindstones, varying from three-fourths of an inch to six or seven inches in diameter are required, and these may be revolved in a small foot-lathe, like the one represented in Fig. 194. Connected with the one here shown is a cabinet work-table, so arranged as to furnish every convenience required by the dentist. It is also so contrived that it may be closed at pleasure, concealing the implements and appliances belonging to it, presenting the appearance of a beautiful piece of furniture. Fig. 194 represents it with

FIG. 194.

FIG. 195.

the upper and lower parts open, exposing the mandrel on which grinding wheels and finishing brushes may be placed, according as the one or other may be needed, as also the wheel and treadle by which they are made to revolve, and several small drawers. In Fig. 195 is shown the work-table, partially drawn out, and the lower part closed.

The teeth being thus arranged and adjusted, a gold plate,

large enough to cover the posterior surface of each, is fitted to them in the following manner: Each tooth has securely fixed in the back part of it two platina rivets, for the purpose of connecting it to the backing. Each backing, therefore, should have two holes punched through it, by means of a pair of dentists' punch forceps, like those represented in Fig. 196, large enough to admit the rivets of the teeth, and of the same distance from each other. After having

FIG. 196

punched one hole, the point of the other may be marked by placing the backing against the tooth, with the rivet nearest the coronal extremity in the hole; then, by moving the strip of gold plate two or three times to the right and left, a mark will be left upon it, indicating the distance the rivets are from each other. The holes on the back part of the plate should be slightly enlarged, and after placing it on the tooth, it is made fast, by very slightly battering, with a light hammer, the ends of the platina rivets, or bending them in opposite directions. If the ends of the platina rivets are struck up so as completely to fill the holes in the backings, it will prevent the solder from flowing in and uniting the two as firmly as it should do. The backings may be slightly hollowed before they are put on. By doing this they each will fit up closely to every part of the back of each tooth, and the plate employed for this purpose should be slightly thicker than that on which the teeth are mounted.

After the backings have been made fast to the teeth, they

are accurately fitted to the plate, and retained by the wax behind them.

The plate, with the teeth and wax on it, after the backings have been put on, are carefully removed from the plaster model, and placed on a large piece of charcoal, using the precaution not to disturb or disarrange the teeth. A paste, made with plaster of paris, asbestos, and water, of the thickness of thin batter, is next poured around them, until the outer surface and coronal extremities are covered to the thickness of half an inch. When this has become hard, the wax may be removed from behind the teeth.

If it should be found, on the removal of the wax, that the backings do not fit accurately to the plate, the apertures may be filled with gold foil or small pieces of gold plate. This done, borax, triturated in water, until of the consistence of cream, is applied with a camel's-hair pencil to all the parts where it is wished that the solder should take effect, not omitting the platina rivets that pass through the backings, as these cannot be made too secure.

Mr. Andrew Wilson adopts a different method in backing mineral teeth. He says, "After having partially fitted the tooth to the plate, take a piece of thick platina foil, as thick as can be used conveniently, and pressing it against the back of the tooth, perforate it where it is marked by the pins; then cut it into the shape of the back as wished to be, and press it as closely as possible to the back of the tooth.

"It will now be requisite to apply a little borax to the platina pins which come through the back, and placing the tooth with its face downwards upon a thin piece of pumice, covered with dry plaster of paris, put several pieces of gold (according to the thickness required) upon the platina back, slowly heat it, gradually raising the heat till it is considered safe to melt the gold with the blow-pipe, when, upon continuing the blast, the gold will rapidly flow over the whole platina surface, incorporating so accurately with the pins in the tooth, that I have never seen a case withdrawn when

the tooth has been broken, during the whole time it has been in use here,* (nearly eight years,) they always remaining firmly fixed in the backing upon the plate.

"After the backing has been run, and the tooth allowed to cool slowly, it is filed to the requisite thickness and shape, when, being closely fitted to the base, it is finally soldered to the plate," in the manner as we have already described. In arranging the teeth on the plate for soldering, Mr. Wilson says, he uses a mixture of equal parts of white sand and plaster, placing a thin strip of platina on the

FIG. 197.

outside of the teeth, with a "layer of the above mixture on both sides of it so that should the plaster crack in soldering, although it is less liable to do so than plaster alone, the platina keeps the teeth from shifting their places. The

* Edinburgh, Scotland.

whole time occupied in heating and backing a tooth is about half an hour, and when several are doing at once, a little longer."

Instead of using the strip of platina plate to prevent the teeth from becoming displaced, in case the plaster cracks, the author has used thin sheet iron.

When the surface of the plate covering the alveolar ridge is very uneven, greater accuracy may, perhaps, be secured in fitting the backings to it, by placing the plate on a piece of charcoal, after the teeth have been arranged, ground up, antagonized and fixed to it with wax, then cover their outer or labial surfaces and coronal extremities with a paste or batter of plaster and asbestos, to the thickness of half an inch. After this has become dry, the wax may be warmed and removed, and the teeth taken off, one by one backed, and then replaced. In this way the backings may be adjusted, and made to fit with the greatest exactness. A piece thus prepared and fixed on charcoal, for soldering, is shown in Fig. 197.

After applying the borax, a number of small pieces of solder, made from recipe No. 1 or 2, are applied immediately on the line of connection between each tooth and the plate, and one over each rivet.

In soldering the teeth to the plate, the heat is applied by means of a large flaring lamp, until the whole mass becomes red, and then by one of about half an inch in diameter, thrown immediately on the line of connection between the backing of a single tooth and the plate; as soon as the solder flows freely here and over each rivet, the flame passed to the adjoining tooth, and so on until the process is completed.

When the solder runs in a wrong direction, the heat, as before stated, should be increased at the point where it is wished that it should take effect.

FINISHING AND APPLYING A PLATE MOUNTED WITH PORCELAIN TEETH.

After the process of soldering is completed, the plaster, as soon as the piece has cooled sufficiently, is carefully removed from the teeth, and the piece placed in a glass or porcelain vessel containing a mixture of equal parts of sulphuric acid and water. As soon as the borax, which, by the process of soldering, has lost its water of crystallization and assumed a glassy hardness, is decomposed, it is removed. This process is termed by jewelers, pickling, and requires from ten minutes to half an hour for its completion, according to the strength of the acid and the quantity of vitrified borax on the plate. After this is decomposed, the acid is washed from the piece, and any rough portions of solder on the plate or backings carefully removed by means of suitable scrapers.

In removing the roughness which may have been occasioned by the imperfect fusion and unevenness of any of the pieces of solder, or from its flowing in a wrong direction, care must be taken not to cut away too much of the plate. After the work has been made as smooth as possible with scrapers, so constructed as to be readily applied and made to act upon every part of the surface of the plate, backings of the teeth and clasps, it may be rubbed with pieces of scotch stone and water until every scratch is removed.

The piece is now placed in a porcelain vessel containing the following mixture :

Pul. nitrate of potass,	℥ ij.
Muriate of soda,	℥ i.
Alum,	℥ i.
Water,	℥ iv.

After boiling for half an hour in this, to decompose the the copper in the surface of the solder, it is boiled a few

minutes in four ounces of water, and one ounce of sub. carb. soda, for the purpose of neutralizing the acid formed by the first mixture, and then washed with a brush in pure water.

The copper being removed from the surface of the plate, the gold will have a beautiful orange color, which it will always retain. The secretions of the mouth will not only fail to tarnish it, but it will be free from the disagreeable taste of which so many wearing artificial teeth applied on plate, complain.

The process of finishing having been conducted thus far, it may be completed by polishing every part of the surface of the plate, backings of the teeth, and clasps, with highly tempered, and finely polished steel burnishers, or a brush-wheel, rotten-stone, and *jeweler's rouge*.* If burnishers are used, they should be frequently dipped in a mixture of water and castile soap, and in using, should be rubbed backwards and forwards in the same direction, until every part of the gold exhibits a high polish. Burnishers of different shapes and sizes will be required for different parts of the work.

A large piece, however, can be polished in much less time, if not more perfectly, with a revolving brush, like the one represented in Fig. 198, turned in a foot-lathe, (see Figs. 194 and 195,) than with burnishers. But, before the rotten-stone is applied, the brush should

FIG. 198.

be lightly smeared with suet, by holding a small piece against it while it is revolving. The rotten-stone is applied in the same manner, and with the brush thus charged, the polishing may commence, but the plate must not be exposed too long to the friction, as it wears it away very rapidly. After the piece has been exposed to

* *Jeweler's rouge* is made by dissolving copperas in water, filtering the solution, and adding a filtered solution of pearlash, or subcarbonate of soda, as long as any sediment falls. The liquor is then filtered again, and the sediment left on the filter, washed by running clean water through it, and then calcined until it is of a scarlet color.—*Chemistry of the Arts*, vol. 2, p. 529.

the action of the brush until all the fine scratches are removed, it is thoroughly washed with a hand-brush in soap and water, then in water, and afterwards rubbed with a piece of soft buckskin, wrapped or sewed around small blunt-pointed pieces of wood, and rouge, until every part is made brilliant.

A very beautiful finish can be given to a dental substitute composed of single teeth mounted on a base, as just described, by placing a narrow collet around each tooth, and soldering it to the plate. This may be done before the teeth are united to the plate ; and it may be made of gold plate or wire, but it must not come down on the teeth more than the sixteenth of an inch. It may be so arranged, as to extend from the backing on one side of each tooth, around to the same point on the other ; and when the proper care is used in fitting it to the tooth, it prevents the introduction of foreign matter between it and the plate. It is to single teeth what a rimmed plate is to gum or block teeth. But when the upper part of the teeth will be exposed in speaking or laughing, it ought not to be applied.

But the best, most beautiful and durable way of mounting single teeth without gums, consists in striking up a second plate over the first, fitting, backing and arranging the teeth on this, then marking with a fine sharp pointed instrument around the buccal and labial sides of each. The teeth are now removed and the back part of the second plate cut away following the festooned line ; this must be done with perfect accuracy, and the festooned outer portion of the plate is slightly beveled from the side in contact with the first plate. This done, the two plates are soldered together, reswaged, the teeth then returned to their proper place, and united to the base in the usual manner. The ends of the teeth in contact with the base, when the work is executed with proper accuracy, have the appearance as they really are, of being embedded in the plate.*

* The above method of mounting teeth, was introduced by Dr. Reynolds, Dentist, of Philadelphia.

In the application of teeth prepared in the manner as just described, it often becomes necessary to make some little alteration in the adaptation of the clasps. This, the operator can always effect, if they have been attached to the plate with the proper care, with a pair of common pliers, and it should be borne in mind that they should never be so applied as to prevent the patient from removing and replacing the piece at pleasure. He should be directed to do this two or three times every day, and each time, to clean the teeth to which the clasps are applied, thoroughly, and it would be well, too, for the artificial piece to be taken out every night on going to bed, and remain out until morning.

The English porcelain teeth are mounted upon a base differently from those manufactured in the United States. They are attached by means of gold wire, soldered to the plate, which pass up through the teeth, and are riveted or soldered.

A substitute for the incisors and cuspidati, thus mounted, is represented in Fig. 199, copied from the work of Dr. James Robinson, on the teeth. This engraving will convey

FIG. 196.

a sufficiently correct idea of the method of attaching the English mineral or porcelain teeth to a metallic base, to render any other description unnecessary. Metallic back-

ings, however, riveted and soldered, in the manner as before directed, is a more secure method of attachment.

CHAPTER ELEVENTH.

MOUNTING NATURAL TEETH UPON A PLATE, OR METALLIC BASE.

NATURAL teeth may be mounted on a plate, constructed in the manner as described for the porcelain, and secured by means of screws or rivets. The latter are preferable to the former. They may also be secured in the following manner: A gold plate is made of the size of the space intended to be supplied with teeth, and about an eighth or sixth of an inch in width. To the inner circle of this, the flat side of a half-round gold wire is soldered, each end extending far enough back to form a clasp around the tooth to which it is intended to be applied. The teeth are next selected and fitted on the model, a horizontal groove is cut across their posterior surfaces, with a saw or file of the same thickness as the plate, so that the plate may be let into them up to the wire, which is afterwards made fast by means of rivets, two in each tooth. This done, all that remains is to fit the ends of the wire to the teeth, on each side of the vacancy, and around the ones they are designed to encompass.

This method of mounting natural teeth, however, is not so good as the one first described, yet, if it be properly done, and the mouth in which they are placed be healthy, they may answer tolerably well for a few years. Teeth applied in this manner, however, seldom last very long, because the groove which receives the plate, admits and retains the secretions of the mouth, which, in a short time, corrode the teeth. When teeth are mounted in the manner as first described, the secretions of the mouth, it is true, get between them and the plates, but then, only one surface is exposed to their

corrosive action ; whereas when secured in the manner as last described, three surfaces are exposed, namely, the one which rests upon the gum, and one on each side of the plate.

But the first method is preferable, for the reason that the gum is pressed upon by a broad, well adapted plate, whereas, when they are fastened in the manner last described, it is pressed upon only by the ends of the teeth, which, as a necessary consequence, produce more or less irritation.

Porcelain teeth, however, since the late improvements made in their manufacture, having almost wholly superseded the use of all other dental substitutes, it is not necessary to enter into a more minute description of the manner of mounting natural teeth on plate.

Having now described the manner of constructing a plate, attaching clasps and teeth to it, and of cleaning and finishing the piece, we shall proceed to notice the manner in which dental substitutes applied in this way should be constructed—giving a sufficient variety of cases to enable the student to determine the proper method of procedure in any one that may be likely to present itself.

CHAPTER TWELFTH.

DENTAL SUBSTITUTES FOR SPECIAL CASES.

IN supplying the loss of natural teeth with artificial substitutes, the ingenuity and skill of the dentist are often taxed to their greatest extent. No two cases are precisely alike, and, therefore, no directions can be given upon the subject from which it will not often be necessary to deviate. The illustrations, however, which follow, will, we trust, from their variety, enable the practitioner to construct an efficient and useful substitute for any teeth, the loss of which he may be called upon to replace.

AN ARTIFICIAL CENTRAL INCISOR FOR THE UPPER JAW, MOUNTED ON PLATE WITH ONE CLASP.

The usual method of applying a central incisor on a metallic base, consists in extending the plate on the palatine side of the teeth on each side of the mouth to the second bicuspid or first molar, and to secure it in the mouth by two clasps, but it is not always necessary to do this; it can often be securely and firmly fixed by extending the plate back on one side, and clasping it to a single bicuspid or molar, and a piece secured in this manner is frequently worn with comfort and satisfaction for years. The author has applied single teeth in this way, when he found it necessary to use clasps, very frequently since 1842, and even two teeth may often be securely retained with one clasp. In extending the plate back in the mouth, it should never be fitted closely around the necks

FIG. 230.

of the teeth behind which it passes, for the reason that it is liable to irritate and inflame the apices of the gums. The author, in common with other dentists, was in the habit of doing this for a long time, but observing the bad effects produced by it, he abandoned the practice many years ago, and has since, in nearly all the cases which he has had, left a space of about an eighth of an inch between the plate and the teeth behind which it passed, until it reached the one to which it was to be clasped. A correct idea of the manner in which a central incisor on plate is applied, may be formed by an examination of Fig. 200. A cuspidatus, or lateral incisor or bicuspid, may be applied in the same way, and if the second bicuspid or first molar is rendered unfit by disease, to clasp to, the plate may be extended to the second molar, or it may be even carried across the mouth, and clasped to a tooth on the opposite side.

AN ARTIFICIAL CENTRAL INCISOR MOUNTED ON A PLATE WITH TWO CLASPS.

FIG. 201.

Cases frequently occur in which it is necessary to employ two clasps for the support of a single incisor, and the accompanying cut, Fig. 201, will indicate the description of plate most proper to be used. The plate as here shown, is extended back, as may be seen, to the first molar on each side, and provided with clasps suitable for this class of teeth.

TWO ARTIFICIAL CENTRAL INCISORS FOR THE UPPER JAW, MOUNTED ON PLATE WITH CLASPS.

In the application of the two upper central incisors on plate, two clasps, one on each side, sometimes become neces-

sary, although they can often be securely and steadily held in their place with one. But generally two should be preferred—and in this case the plate may be extended back, like the one represented in Fig. 201, on each side along the alveolar ridge to the first permanent molar, but if this is defective, it may be carried to the second molar, and in case this should be so much impaired by disease as to render it unfit to be clasped to, it need not extend further back than the second or even the first bicuspid. When the teeth are lost on one side of the mouth, it may be extended back on the other, and secured by two clasps on that side, as, for example, to the second bi-

cuspid and second molar, or to any other two teeth which may offer a firmer and more secure support.

Fig. 202 represents two central incisors mounted on plate and intended to be clasped to the first mo-

FIG. 202.

lar on each side of the mouth. For a similar case in the lower jaw, one clasp may be made to hold the piece.

ARTIFICIAL INCISORS AND CUSPIDATI FOR THE UPPER JAW, MOUNTED ON PLATE, WITH CLASPS.

FIG. 203.

The construction of the plate represented in Fig. 203, is upon precisely the same principle as the preceding, and the only difference is, that the part of the plate on

which the teeth are mounted fills a larger vacancy in the alveolar arch. And, as in the former case, when the teeth on one side of the mouth are too much decayed, or are incapable of affording a secure attachment, even this number

of teeth may be held by two clasps on one side of the mouth, and they are often applied with but one, but whenever this is done, the plate should be extended half or three-fourths of an inch back of the tooth to which it is clasped. If this precaution is neglected, the piece, from its weight, will act as a lever upon the tooth, and soon loosen it and cause it to drop out.

TWO ARTIFICIAL BICUSPIDS FOR THE UPPER JAW, MOUNTED ON PLATE WITH ONE CLASP.

FIG. 204.

The manner of constructing a substitute for two upper bicuspids on the same side of the mouth, is exhibited in Fig. 204, but when the adjoining first molar does not offer a suitable support for the piece, the plate may be extended back on the inside of it, and secured by a clasp to the second, and if this also is diseased, or has been removed, the plate may be carried across to the opposite side of the mouth, and secured to such teeth as may there offer the best means of attachment. But in this, as in other similar cases, the plate should be thick, and adapted with the most perfect accuracy to the parts against which it is to rest. If the clasp or clasps, if more than one is applied, are of the proper width, and well adapted, the teeth will be held firmly in place, and be worn without inconvenience.

ARTIFICIAL BICUSPIDS AND FIRST MOLARS FOR THE UPPER JAW, MOUNTED ON PLATE WITH CLASPS.

FIG. 205.

The usual plan of constructing a plate for a dental substitute like the one named above, is to cover the parts of the alveolar ridge to be supplied with artificial teeth, extending the plate across immediately behind the front teeth, and confining the posterior extremities with clasps applied to the second molars.

It is thought that greater stability may be given to the piece by using two separate plates and connecting them together by means of a strip of thick plate passing up under the palatine arch, in the manner as shown in Fig. 205. This method of connecting two pieces, was described to the author in 1844, by the late Dr. L. Roper, of Philadelphia. It will also be found valuable for giving stability to a narrow atmospheric pressure plate for an entire upper set of teeth.

ARTIFICIAL INCISORS, CUSPIDS AND BICUSPIDS FOR THE UPPER JAW, MOUNTED ON PLATE, WITH CLASPS.

When the crowns of the first molars of the upper jaw are long, and well developed, and in a healthy condition, the loss of the ten anterior teeth may be replaced with an artificial substitute that will subserve the purposes of correct enunciation, as well as the natural organs, and upon which mastication may be conveniently performed. The teeth, however, should be attached to a thick strong plate, and secured to the first molars by broad clasps. They should also be correctly and accurately antagonized, for upon this will their utility in a great measure depend. The plate, too, should extend back of the teeth to which it is clasped, and when the second molars and *dentes sapientiæ* are wanting, it may cover the whole of the alveolar ridge, in the manner as represented in

FIG. 206.

. 206, but if these still remain, it may rest upon the alveolar ridges on the palatine side, but without touching the teeth.

ARTIFICIAL INCISORS, CUSPIDS, BICUSPIDS, FIRST RIGHT, AND FIRST AND SECOND LEFT MOLARS FOR THE UPPER JAW, MOUNTED ON PLATE WITH ONE CLASP.

The dentist is sometimes called on to replace the loss of upper teeth, when there is only a single molar remaining. It would, unquestionably, be better, in cases of this sort, to

FIG. 207.

to remove the remaining tooth and apply a whole upper set on the atmospheric pressure principle, but this, he is not always permitted to do. In this case, he may either apply a clasp to the remaining tooth, or, what is perhaps much better, use a suction plate. In securing a plate sustaining so many teeth, it should be very thin and closely fitted to the gums.

The teeth, too, should be thin. The author has applied upper sets of teeth in this way, which are worn without the slightest inconvenience, and that have realized his most sanguine expectations. As in the case of the description of the dental substitute last noticed, the clasp should be wide, and accurately fitted to the tooth. (See Fig. 207, in which is represented a set of teeth of this description.)

ARTIFICIAL LATERAL INCISORS, AND LEFT BICUSPIDS FOR THE UPPER JAW, MOUNTED ON PLATE WITH TWO CLASPS ON ONE SIDE.

It often happens that there are several vacuities in the alveolar ridge which the dentist is called upon to fill, and the insertion of artificial teeth in cases of this descrip-

tion always require more judgment and mechanical tact and skill, than in filling only a single aperture. After obtaining a plaster model, the teeth on it should be removed before metallic casts are made, and a plate swaged up over the entire ridge, and the parts of it which cover the places occupied by the remaining teeth filed out in the

FIG. 208.

manner as described in another place. The accompanying cut, however, will serve to illustrate the manner of constructing dental substitutes in all cases of this nature, but this, as may be perceived, is intended to be secured in the mouth by two clasps on one side of the alveolar ridge—all the teeth on the other having been lost.

The plate in the case here represented, might have been extended further back, and the first and even second molar replaced, but they were dispensed with, for the reason that there were no teeth further back in the lower jaw than the second bicuspid for them to antagonise against.

We have given the foregoing illustrations of partial sets of artificial teeth, as the use of clasps are sometimes required, but these may be dispensed with in at least nineteen cases out of every twenty. It rarely happens that any other support than suction is necessary.

CHAPTER THIRTEENTH.

THE TEETH TO WHICH IT IS MOST PROPER TO APPLY CLASPS, AND THE MEANS NECESSARY TO PREVENT THE INJURY LIABLE TO RESULT FROM THEIR USE.

BEFORE we proceed to describe the manner of applying a dental substitute with spiral springs, or upon the atmospheric pressure, or suction principle, it will be proper to offer a few remarks upon the teeth to which it is most proper to apply clasps, and the means necessary to prevent the injurious effects liable to result from their use.

Some teeth, owing to their situation in the dental arch and the shape of their crowns, offer a more secure means of attachment to a dental substitute retained in the mouth by clasps than others, and in selecting those which are to be used for this purpose, the exercise of some judgment is often called for. There are many circumstances, however, which should influence the decision of the dentist in this matter. Some of these we shall presently notice.

But, as we have stated in another place, the first molars in the upper jaw, when sound and securely articulated, offer a better means of support to a dental substitute, than any of the other teeth, and when they can be as conveniently employed for this purpose, they should be preferred. Next to these teeth, the second molars, in most cases, are the best. But when neither the first nor second can be used with safety, or when they have been lost, or are so much injured by disease as to render them an insecure means of attachment, the second bicuspid may be employed. After the last mentioned teeth, the first bicuspid is the next best,

and when from the loss or diseased condition of these, they cannot be used, the *dentes sapientiæ*, if sound, well developed and firmly articulated, may be employed.

A clasp should never be applied to a loose tooth, or to one situated in a diseased socket, or which is so much affected by caries, as to render its perfect restoration and permanent preservation impracticable, and when none but such can be had, the proper course to pursue, is to extract every tooth in the jaw, and replace the loss of the whole with an entire upper set. The application of clasps to diseased or loose teeth, always aggravates the morbid condition of the parts, and causes the substitute which they sustain, to become a source of annoyance to the patient. Besides, such teeth can be retained in the mouth only for a short time, and when they give way, the artificial appliance becomes useless, and even while it is worn, it is not held firmly in its place, but is moved up and down by the action of the lips and tongue, so that its presence can hardly escape observation from the most careless observer.

The crowns of the *cuspidati*, being of a conical shape, are wholly unsuited for the retention of clasps, and, consequently, should never be used for this purpose, if it be possible to avoid it. There are some cases, however, in which it becomes absolutely necessary to apply clasps to them, as for example, when the loss of an incisor is to be replaced with a substitute attached to a narrow plate, and where none of the back teeth are remaining or in a condition to be used as a means of support to the plate. In this case, the clasps should be narrow, and adapted with the greatest accuracy, and this becomes the more essential, as it is necessary that they should be short to prevent being seen. They should also be applied near to the gums, but not near enough to touch and irritate them.

The incisors offer a poorer means of attachment for a dental substitute than any of the other teeth. It is exceedingly difficult to apply clasps to these teeth in such a manner as to retain even a single tooth with sufficient stability to be

worn with any degree of comfort, yet when they are the only ones that can be used, it may sometimes be necessary to apply them even to these teeth, but only as a dernier resort.

Finally, there are many circumstances which it is necessary to take into consideration in the selection of teeth to be used as a means of support for artificial teeth. For example, a space should never be filed between two sound molar or bicuspid teeth for the purpose of applying a clasp, if there is another tooth around which it can be placed without this operation. The liability of a tooth to decay, to which a clasp is applied, is always greatly increased by the removal of a portion of its substance. Hence, the separation of two teeth with a file, with a view to the application of a clasp to one of them, should never be resorted to, if it be possible to avoid it.

With regard to the lower jaw, parts of sets are much less frequently called for here than in the upper, and when they are, the use of clasps may be often dispensed with altogether. But it sometimes becomes necessary to use them, and, as a general rule, they can be more conveniently applied to the bicuspids than the molars or cuspids. A clasp can seldom be applied, advantageously, to a lower molar.

If the injurious effects liable to result from the application of clasps to teeth, could not, in any way, be counteracted, dental substitutes, maintained in the mouth by this means, would, in the majority of cases, be productive of more injury than benefit. But, fortunately, the deleterious effects liable to result from them may, in most cases, to some extent at least, be prevented. They are not produced, as many have erroneously supposed, by the mechanical action of the clasps upon the teeth, but by the chemical action of the secretions of the mouth, and other extraneous matter retained between the two.

The cause of this destructive action, then, being chemical, and not mechanical, the means of preventing its deleterious effects, are obvious. They consist, as we have stated in

another place, in the frequent removal of the artificial teeth, and thoroughly cleansing the natural organs used as a means of support for them. This should be done every morning and night and after each meal. For which purpose, a brush and waxed floss silk may be employed, and the teeth rubbed until every particle of clammy and vitiated mucus and foreign matter is removed. The inner surface of the clasps, too, should be freed from all impurities, and the whole piece cleansed with a brush and water.

The clasps should always be so constructed, that they may be removed with ease by the patient. But the effects arising from the presence of corrosive agents are not the only deleterious consequences liable to be produced by clasps. They are often fitted and applied in such a manner as to force themselves up upon the necks of the teeth and gums, causing inflammation of the latter, as well as that of the alveolo-dental membrane, and, ultimately, the destruction of the alveoli and loss of the teeth. The same effects, too, are produced when they act as retractors. Hence, the necessity of adjusting them in the most perfect manner.

CHAPTER FOURTEENTH.

DOUBLE SET OF ARTIFICIAL TEETH MOUNTED ON PLATE WITH SPIRAL SPRINGS.

FIG. 269.

By a double set of artificial teeth, is meant a substitute for all or the greater part of the natural teeth of both jaws. They are sometimes, though now very rarely, confined in the mouth with spiral springs, one on each side, attached at each end, to each circle of teeth. When correctly con-

structed, and applied under favorable circumstances, they are valuable substitutes for the natural organs, but when badly constructed, as they frequently are, and applied under unfavorable circumstances, they are productive of more or less inconvenience and annoyance to the patient.

It often happens, that the loss of the teeth is occasioned by disease in the gums and alveolar processes, and when this is the case, the latter are so much wasted and destroyed that the ridge in the lower jaw is scarcely perceptible and becomes covered with loose folds of mucous membrane. The application of a useful dental substitute, under such circumstances, is sometimes attended with difficulty. The pressure of the piece is apt to cause irritation. But this may, in most cases, be prevented by using a thick plate, fitted accurately to the parts and extended back upon the coronoid processes. It should also be applied without springs.

The upper plate may be about one inch in width, and the

lower as wide as the ridge will admit of its being made, and three times as thick as the upper, and of gold at least twenty-two carat fine. Twenty carat gold may be used for the upper plate.

After having obtained a correct antagonizing model, the operator places a rim of beeswax on each plate against which the teeth are arranged as he selects them, beginning with the central incisors, the upper first, then the lower, next the laterals, afterwards the cuspids and bicuspid, and, lastly, the first and second molars—twenty-eight being the number usually employed for an artificial set.

After the teeth have been arranged, and fitted to the plates, and the gold backings put on, they may be secured with plaster; the wax is then removed, and the process of soldering and finishing performed in the manner as already described.

But before the teeth are soldered on, the attachments for the springs are made fast to the outer edge of the plates on each side, against the second bicuspid, or partly between them and the first molars. The description of attachments which the author prefers, so regulates the motions of the springs, that they are prevented from coming in contact with the outer surface of the alveolar ridge on the outside of the plate, or from turning out towards the cheek, and irritating the mucous membrane. Their construction is so plainly exhibited in the accompanying cut, as well as that of the eyelets and springs, that no other description is deemed necessary.

FIG. 210.

The principle on which the springs act, may be seen in Fig. 209, by which it will be perceived the upper and lower rows of teeth are constantly, but gently pressed against the parts on which they rest.

The length of the springs must be determined by the distance of the jaws from each other when the mouth is opened. In some cases it is necessary to have them much longer than in others. The usual length, however, is from an inch and a half to two inches.

It often happens that six or eight teeth in the front part of the mouth in the lower jaw remain healthy and firmly fixed in their sockets, after all the other teeth are lost. In this case, the lower plate may be so constructed as to cover the unoccupied portions of the alveolar ridge, and to fit its upper and inner surface behind the remaining natural teeth. This part of the plate is strengthened by soldering to it another plate of equal or even greater thickness.

But when the lower incisors, cuspids, and two of the bicuspids are remaining, it is better to dispense with the others than encumber this part of the mouth with artificial substitutes. The upper teeth may be replaced, but not the lower, and when there are but six remaining in the inferior maxillary, it would be better to remove them and apply an entire dental apparatus, as it is exceedingly difficult and sometimes impossible to replace the others in such a way as to render them serviceable while the front part of the jaw is occupied with natural teeth, especially when retained in place by means of spiral springs.

CHAPTER FIFTEENTH.

ARTIFICIAL TEETH MOUNTED ON SUCTION OR ATMOSPHERIC BASES.

THE engraving, Fig. 211, represents the appearance of a dental substitute for all the upper teeth, when ready to be put in the mouth, and Fig. 212 the plaster model of the alveolar ridge and roof of the mouth of the individual for whom the teeth, from which the first of these drawings was made, were intended. The only difference between teeth, applied upon this principle and with spiral springs, is, the plate in the former is rather wider than in the latter. It covers the whole of the outer surface of the alveolar

FIG. 211.

FIG. 212.

ridge, and a considerable portion of the roof of the mouth, but it need not go as far back as many dentists are in the habit of extending it, for the reason that a very wide plate cannot be as perfectly and accurately adapted to the parts as one of moderate width. Unless it be made to touch every por-

tion of the surface which it covers, it will be constantly liable to drop. A narrow plate, well fitted, will adhere more firmly than a very wide one, imperfectly adapted. The successful application of artificial teeth, upon this principle, depends upon having the plate accurately adapted to the parts upon which it is to rest.

However accurately a plate may be made to fit the model, it is sometimes warped in soldering the teeth to it, destroying its adaptation and causing it to rock when placed in the mouth. When this happens, it cannot be made to adhere to the gums, and consequently cannot be worn with comfort. For the restoration of the plate, a variety of means have been proposed. The one which the writer has found most successful, consists in binding it to the plaster model with a fine iron wire in such a way that it shall be made to touch every part it covers ; then to heat the piece to a cherry red heat with the flame of a lamp applied with a blow-pipe.

The springing of the plate in soldering on the teeth being caused by unequal expansion of the gold, it might nearly always be prevented by annealing it after the swaging has been completed. In striking up the plate, some parts are acted upon and hardened more than others, and this is the cause of its unequal expansion. It is also important that the gold placed upon the teeth should be annealed before being soldered to the plate. But with all the care and precaution that can be used, it is not possible, in every case, to secure absolute accuracy of adaptation, as the dies between which the plate are swaged are necessarily more or less bruised in this part of the operation.

In the application of a double set, on this principle, the lower plate should be as wide and long as the alveolar ridge of the inferior maxilla will admit of its being made. Fig. 213 represents a dental substitute of this description in an antagonizing model of plaster of paris. The posterior extremities of the lower plate, as may be perceived, extend up about half an inch on the coronoid processes. The lower

alveolar ridge of the individual, (a lady,) for whom the original was constructed, is almost wholly wanting, and each side is covered with loose folds of mucous membrane, so irritable as to prevent the patient from wearing artificial teeth applied with springs. She has worn the set here represented many years without having experienced the slightest inconvenience.

FIG. 213.

In the substitution of artificial for the loss of the natural teeth, of either or both jaws, this method, when it can be advantageously adopted, and there are few cases in which it cannot be, is preferable to any other.

When the teeth are put in the mouth, the patient is directed to exhaust the air from between the plate or plates, when a double set is applied, and gums, which, if properly fitted, will at once cause them to adhere, though not immediately with as much tenacity as they will after having been worn a few days or weeks.

It is not always necessary to employ a very wide plate to secure a sufficient amount of suction for its retention. A comparatively narrow one may often be made to adhere with very great tenacity to the gums. But a plate of this kind is more liable to be bent, and lose its perfect adaptation to the parts than a wide one. Its liability to be

FIG. 214.

injured, however, in this way, may be measurably prevented by extending a piece across from one side to the other, under the palatine arch, in the manner as recom-

mended by Dr. Roper for two or three teeth on each side of the jaw, as shown in Fig. 214. In this way, great stability may be given to a plate for an upper circle of teeth, without encumbering the mouth with a wide plate. It may also be used with great advantage in cases where it is necessary to employ spiral springs.

In replacing the loss of the bicuspid and molars of the upper jaw with artificial substitutes, mounted upon an atmospheric or suction plate, increased stability may be given to the piece by constructing and adjusting the plate in such a manner that a narrow band shall pass in front of the

FIG. 215.

FIG. 216.

alveolar border, as represented in Fig. 215, but this should fit with great accuracy to prevent irritating the gums. This method of constructing and applying atmospheric plates was recommended to the author by Dr. G. E. Hayes, of Buffalo, N. Y. In Fig. 216 is represented a substitute for all the upper teeth except the *dentes sapientiæ*, constructed upon the same principle.

In the application of one or two teeth upon this principle, it is necessary to employ a very wide plate, in order to present as much surface for the atmosphere to act upon as possible. A substitute for the two central incisors mounted upon a single plate, to be applied upon this principle, is represented in Fig. 217.

FIG. 217.

ARTIFICIAL TEETH WITH GUMS, MOUNTED ON PLATE.

The loss of the teeth is sometimes followed by the destruction of more or less of the alveolar border. When this happens, in furnishing a substitute for the former, it often becomes necessary for the restoration of the contour of the face, to replace the latter; and for doing which several methods of procedure have been adopted.

FIG. 218.

When ivory was employed for artificial teeth, and as bases for the support of dental substitutes, it was carved in such a manner as to imitate the shape of the gums, and afterwards colored. But the use of this substance for purposes of this kind, has been wholly abandoned, or very nearly.

Raised plates have also been employed, and these may often be made to answer a very good purpose, but since the invention of porcelain teeth, a much better substitute for the alveolar border and gums has been used. Porcelain teeth may be manufactured either singly or in blocks, with a base, colored and enameled on the exterior or labial surface, forming a most excellent substitute for the lost structures, and imitating nature so closely as almost to preclude the possibility of detection. It has been customary among dentists manufacturing their own porcelain or mineral teeth, in the construction of an entire set, or a series for the same

jaw, to fabricate them in blocks, but as few dentists possess the means and necessary knowledge and practical experience for doing this, and as there are some cases in which they cannot be advantageously employed, a few remarks on the use of single gum teeth may not be out of place. In a subsequent chapter, the method of making and mounting block teeth, will be described.

A little more time and tact are required in fitting the teeth to each other, and to the plate, than for the manufacture of blocks, but when properly adjusted and attached to the plate, they answer, in very many cases, almost as good a purpose, and if by any accident, one or two of the teeth are broken, they may be more easily replaced.

But in the construction of a piece composed of single teeth, they should be fitted to each other and the plate in the most perfect and accurate manner, so that no lodgments may be afforded for particles of food or extraneous matter of any kind. In Fig. 218, is represented an atmospheric pressure or suction substitute for all the teeth of the upper jaw, composed of single gum teeth, mounted upon a broad plate. In Fig. 219 is seen a representation of a set of gum teeth for the superior maxillary, mounted on a base of the same kind, with the outer edge of the plate turned down on the teeth.

FIG. 219.

It sometimes happens in the application of a substitute for all the teeth of the upper jaw upon the atmospheric principle, that the ridge is so prominent as to preclude the use of gum teeth, and to expose the plate covering

the anterior part of it, whenever the mouth is opened in speaking or laughing. To obviate this, it has been recommended to cover the anterior margin of the plate and interspaces between the teeth with a terra-metallic paste, fusible at a very low temperature, and afterwards covered with gum enamel. The following formula is given by M. Delabarre

for this purpose : porcelain paste 1 oz., white silex half oz., any oxyd 10 grs., and a sufficient quantity of calcined gypsum to give to it the necessary degree of fusibility. As a suitable enamel, Desirabode recommends, feldspar 2 drachms, oxyd of gold 6 grs., kaolin 6 grs. But neither of these formulas can be used on gold plate, nor in connection with American porcelain teeth, as too high a heat is required for their fusion. Drs. Hunter and Allen, of Cincinnati, Ohio, however, have succeeded in making a silicious composition, which can be used on gold slightly alloyed with platina. The manner of working this will be described in a subsequent chapter.

CHAPTER SIXTEENTH.

ARTIFICIAL TEETH MOUNTED ON CAVITY PLATES.

A METALLIC base for artificial teeth may be made to adhere to the gums with greater tenacity by having it constructed with a cavity opening upon them, than by simple coadaptation, however accurately the plate may be made to fit. Still, in the majority of cases, it may be made to adhere with sufficient tenacity for all useful and practical purposes, and if a plate of this kind can be so applied as to secure *perfectly* the *atmospheric principle*, no advantage whatever is derived from a chamber in the plate, opening upon the gums. But this, in many cases, is found to be impracticable, for the reason as stated by Dr. Dwinelle, that when the plate is applied, and an effort made to exhaust the air from between it and the gums, the latter, "along the line, and behind the edge of the former, are drawn down so as to meet it," thus resisting every effort made from without to withdraw the air from the central part of the plate, so that the pressure of the atmosphere is only exerted upon a small breadth of surface, along the edge of it, where the suction is constantly liable to be disturbed in biting upon the teeth. With a view of obviating this difficulty, the idea of constructing a plate with a cavity, suggested itself to the writer as early as 1835, which he mentioned at the time to several of his professional brethren, but as the construction of the chamber which he then devised was found objectionable, he abandoned the use of it, and it was not until the early part of 1848, when he had an opportunity of seeing a cavity plate contrived by Dr. J. A. Cleaveland, that he was again induced to construct a base of this sort. Dr. C. had construct-

ed cavity plates two or three years previously to this time. Dr. W. H. Dwinelle made a cavity plate with an external opening and valve for exhausting the air, in the winter of 1845 ; and in the summer of 1847, or '48, Dr. Jahial Parmly exhibited to the author a plate with a simple cavity struck into it in swaging. Some months after, he heard, for the first time, of a cavity plate, contrived and patented by Mr. Gilbert, of New Haven.

The cavity in most of the plates now employed, is formed nearly in the centre, or immediately behind the alveolar ridge, but Dr. J. F. B. Flagg, a dentist of Philadelphia, has recently added two lateral cavities, which is said to prevent the plate from rocking, and to give to it increased stability.

Having premised these few remarks on the subject of cavity plates, we shall proceed to give a brief description of the manner of constructing them ; beginning first with the cavity-plate and valve of Dr. Dwinelle.

To the plaster model, a piece of wax about an eighth of an inch thick in the centre, and five-eighths in diameter, but gradually diminishing to the periphery, is placed just behind the alveolar border. With the model thus prepared, a metallic model and counter model are obtained. A plate is then struck up in the usual way, then with a very small drill a hole is made through the central part of the cavity, or raised part of the plate. This is next reamed out to a cone shape, the base terminating outwards, and not exceeding half a line in diameter. A piece of gold wire as large as the base of the hole is now taken, and filed down in a small jeweler's bow-lathe until it nearly fits the conical hole in the plate, leaving an extension to pass up through the plate in the form of a stem. It is again placed in the lathe and ground down with powdered scotch stone and oil, until it fits the cone-shaped hole in the plate so perfectly as to render it completely air-tight ; the base is then filed down to a level with the plate.

The method which Dr. Dwinelle adopted for securing this

valve is as follows, we copy his own description: "Having rolled down a piece of gold to exceeding thinness, we cut out a piece in the form of a cross; at the centre, where the angles met, we punctured a hole to receive the stem of the valve bending the four extremities downwards equally, we formed what artizans would call a spider-leg spring. Now, the valve being in its place, we placed the spring immediately over it, on the upper surface of the plate, and pressed it down—the stem of the valve passing through the hole in the centre of the spring, until it reached within about half a line of the plate; with a small pair of forceps, we then seized the stem above the spring, and by pressure, flattened it down, so as to form a kind of head, thus detaining it attached, and holding it to its place." Dr. D. states, however, that he has subsequently used a spring made of a single strip of gold, with one end attached to the plate, like a tongue to an accordeon, making a simple slit in the end of it for the reception of the stem of the valve. He also recommends that a piece of plate be soldered on the part of the chamber pierced by the hole to increase its thickness.

FIG. 220.

FIG. 221.

In Fig. 220 is represented an enlarged view of the valve and socket *a a* without the spring; also showing the raised part of the plate *b b*, in which the conical valve *a a* is fitted. In Fig. 221, the valve spring and plate combined, are represented.

In exhausting the air from the cavity, and between the plate and gums, the valve is drawn down, which gives it an opportunity of escaping, but the instant it passes up to its place, its further egress, and ingress from without, is prevented.*

The next description of cavity plate which we propose to notice is the one contrived by Dr. J. A. Cleaveland, and the following is the method of procedure in its construction:

* Vide Dr. Dwinelle on Cavity Plates, in No. 2, vol. x, Amer. Jour. of Den. Sci.

A metallic model and counter-model having been obtained, a plate is struck up covering the entire alveolar border and extending back as far as the termination of the hard palate. This done, it is placed in the mouth, and if it be found to be accurately adapted to the parts against which it is placed, it may be removed, and a piece of half round wire of the same metal, as large as a common sized knitting needle, soldered to the lower side of the plate, immediately behind the alveolar ridge, describing a circle about the size of an American twenty-five cent piece. The part within the circle is next removed; the plate then placed on the model, and a piece of softened beeswax, about a tenth or twelfth part of an inch in thickness, having a circumference one-fourth greater than the hole in the plate, is placed over the opening, extending a short distance beyond the wire on every side. At the periphery it is brought to a thin edge, and is much thinner in the centre than where it covers the wire surrounding the opening in the plate. A wax impression of the model, plate and wax covering the opening in it, is next taken. From this, a plaster and metallic model and counter-model are obtained. A thin plate of gold, if the first plate be of this metal, large enough to cover the wax on the first plate, is now struck up; the wax is next removed from the first plate, and the last soldered to it, when, if the piece be applied to the mouth and the air exhausted, it will be found to adhere with great tenacity.

FIG. 222.

A sectional view of the cavity is represented in Fig. 222.

The principal advantage of Dr. Cleaveland's cavity plate, is this: by the union of two plates, the liability of disturbing that portion of the base which covers the roof of the mouth, in biting against the teeth is greatly diminished.

The base being thus prepared, the teeth may be mounted upon it in the manner described in a preceding chapter.

The simple cavity plate employed by Dr. Jahial Parmly, of New York, and patented by Mr. Gilbert, of New Haven, may be formed with as much ease as the ordinary plate, and in most cases, will answer as well as any other description of cavity plate. The method of procedure in forming a plate of this sort is, first, to place a piece of softened wax on the model, over the median line, immediately behind the alveolar border. In the centre it should be about the tenth part of an inch in thickness, gradually diminishing to the circumference, and about three-fourths of an inch in diameter. With the model thus prepared an impression is made in sand, and a metallic model and counter-model procured. This done, the plate is struck up in the usual way, and the teeth arranged, fitted and attached to it, in the manner already described.

FIG. 223.

In Fig. 223 is represented a sectional view of a plate of this description. If it is desired to have lateral chambers in the plate, three pieces of wax are placed on the plaster model instead of one. One may be placed in the centre, as already described, and one on the alveolar ridge on each side. But this can only be done in forming a plate for the upper jaw. A plate for the lower jaw can only have lateral chambers, but these may extend forward, and even meet in front.

The remarks which we have thus far made upon cavity plates, apply to a base for a substitute for all the teeth of one jaw; but increased adhesion and stability of such pieces are not the only advantage gained by the use of this description of plate. With a cavity plate, the loss of a single tooth, or any number of teeth, may, in most cases, be replaced without the aid of clasps, and when this last means

of support for artificial teeth can be dispensed with, it should be done. The deleterious effects liable to result from their use have already been noticed. So successful has the use of cavity plates been in the hands of the author, that he rarely finds it necessary to employ clasps.

The size of the plate which he employs for a single incisor, or for two or three front teeth, is indicated by the dotted line on the plaster model, as represented in Fig. 224. The size of the cavity may also be seen by the wax placed in the centre of the circle formed by the dotted line.* When more than two or three teeth are required, a larger plate may be employed.

FIG. 224.

We have thus far only spoken of the advantages of cavity plates. We shall now notice one or two of the disadvantages liable to result from their employment. In the first place, the protuberance on the lower part of the plate interferes, in some degree, with the movements of the tongue and with the articulation of words, but it becomes less and less mani-

* But the wax here represented is much thicker than is necessary. A cavity the sixteenth part of an inch in depth, will, in most cases, be found amply sufficient.

fest the longer the piece is worn, until ultimately the individual almost ceases to be conscious of the presence of any foreign body in his mouth. But there is another and more serious objection, and it is this: there is a constant tendency of the mucous membrane, over the cavity, to thicken and come down into it, assuming a sort of hypertrophied condition, and in some cases it has ulcerated. We have not, however, met with many cases in our own practice in which this has happened. But this morbid tendency may, in nearly every case, be prevented, by leaving the piece out of the mouth during the night; and the shallower the cavity, the less will be the liability to it.

CHAPTER SEVENTEENTH.

PORCELAIN BLOCK TEETH.

THE perfection to which the manufacture of block teeth has now arrived, renders this description of substitute for the loss of the natural organs, in those cases where artificial gums are required, superior, in many respects, to single gum-teeth. The objections that formerly existed to their use, have, one after another, gradually disappeared before the march of improvement, which has been as actively and as successfully at work in this, as in any other department of science or art. But more time, and close, and persevering application are necessary to obtain a thorough knowledge of this than almost any other branch of practical dentistry. The preparation of the various materials which enter into the composition of block-teeth, requires at least, some knowledge of chemistry, and to put these materials together after they have been prepared, and construct from them a dental substitute of this kind, demands the nicest and most skillful manipulation. The slightest error in the preparation or mixing of the materials, will often give a result entirely different from the one aimed at, and teeth made by different persons, from the same recipe, frequently differ very widely in appearance, depending on the manner in which they have been worked.

In the description which we propose to give of the manner of making and mounting block teeth, we shall begin by enumerating the materials that enter into their composition.

MATERIALS USED IN MAKING PORCELAIN BLOCK TEETH.

Porcelain teeth are composed of two portions ; one is call-

ed the body or base, and the other the enamel. The body is composed principally of *feldspar*, *silex*, and *kaolin*; and the enamel, of *feldspar*, with a small trace of *silex*. With these, various metallic oxyds or metals, reduced to a state of minute division, are mixed, for the purpose of imparting the necessary color.

Feldspar.—This mineral occurs in a crystallized state, in the form of oblique, rhomboidal prisms, and is of a white, gray, red, brown, green, yellow, or bluish color. But the only kind suited for use in the manufacture of porcelain teeth, is the pure white. It consists, according to Rose, of silica, 66.75; alumina, 17.50; potash, 12; lime, 1.25; and oxyd of iron, 0.75. It is found near Boston, at New Bedford, Oakham, and West Springfield, Massachusetts: near Philadelphia, Pa.; near Wilmington, Del.; at Ticonderoga, N. Y.; near Baltimore, Md.; and in various other places in the United States. But the Wilmington, Del.; Philadelphia and Boston spars are regarded as the best varieties for use in porcelain block teeth.

Previously to use, it is put in a furnace and heated nearly to a white heat, then thrown into cold water. It is now broken into small pieces; freed from impurities, and ground in a mortar or mill, to fine powder, or, until it will pass through a sieve of No. 9 bolting cloth. This is easily fused and when mixed with *silex* and *kaolin*, diffuses itself, in baking, throughout the mass, imparting to it a semitranslucent appearance.

Silex.—Flint, quartz, and white sand are the purest varieties of *silex*, but for porcelain teeth the crystalline form is the best; and this is found in great abundance in various parts of the United States. It is prepared for use by heating it to a white heat, then plunging it in cold water, and afterwards reducing it to a fine powder in a quartz or wedge-wood mortar.

Kaolin.—This is the Chinese name for *porcelain clay*, which is the result of the decomposition of mineral feldspar, and consists of nearly equal proportions of alumina and silica. It is of a yellowish or reddish white color when pure, and is found at Fairmount, near Philadelphia; near Wilmington, Del.; at Montonk, Vermont, on the Columbia rail road; at Washington, Ct.; in Missouri; and in South Carolina.

It is prepared for use by washing in clean water. After the courser particles have settled to the bottom of the vessel, the water in which the finer ones are suspended is poured off into a second vessel, where it is permitted to remain until the whole of the kaolin has settled to the bottom. The water is then poured off, and the kaolin dried in the sun.

There are other varieties of clay which have been found to answer quite as well as the porcelain. That which shrinks least, is, of course, preferable. Two kinds are found near Baltimore, which shrink but very little in baking; one is of a grayish white, and the other, of a bluish white color. But less importance is attached to clay as a constituent of porcelain block teeth, at this time, than formerly. Many dispense with the use of it almost altogether.

COLORING MATERIALS.

The materials used for coloring porcelain teeth, are, as we have before stated, metals in a state of minute division or, metallic oxyds mixed in certain proportions with the body or enamel, or both. The following are the principal metals and oxyds employed for this purpose:

<i>Metals and Oxyds used.</i>	<i>Color given.</i>
Gold in fillings and its oxyds, . . .	Bright rose red.
Platina sponge or fillings, . . .	Grayish blue.
Purple powder of cassius, . . .	Rose purple.
Oxyd of titanium, . . .	Bright yellow.

Oxyd of uranium,	Greenish yellow.
Oxyd of manganese,	Purple.
Oxyd of silver,	Lemon yellow.
Oxyd of cobalt,	Bright blue.

Of the above, the oxyds of gold, platina sponge and titanium are the most important. With these, nearly every color and tint required may be obtained.

Metallic Gold.—This may be prepared for use by grinding gold in filings, or in leaf with a small quantity of spar in a mortar or on a slab until reduced to a fine powder; or if there be any doubt with regard to its purity, the following method may be adopted. Melt in a crucible with borax, 12 parts pure silver, 4 parts gold and one part tin, stirring, while in a fused state, until the gold and silver are well mixed; it may then be poured into an ingot mould, rolled very thin and cut into small pieces, or granulated by being poured into a vessel containing water which is rapidly revolving. The whole mass is now collected, put into an evaporating dish and nitric acid poured on. When this has become completely saturated with the silver, it is poured off in a vessel containing water, and fresh acid poured on and the action continued until the whole of the silver is decomposed or dissolved, which may be known by the colorless appearance of the fumes. The pure gold remaining at the bottom of the dish is washed until completely free from acid. A simpler method of obtaining a fine powder consists in precipitating a solution of chloride of gold by means of protosulphate of iron; then washing the precipitate with dilute muriatic acid to remove the adhering iron, and afterwards with water to remove the acid.

Oxyd of Gold.—Dissolve gold foil or pure gold in *aqua regia*, composed of one part nitric and two parts muriatic acid; dilute the solution with water and precipitate the gold with *aqua ammonia*, using the precaution not to add more

than is required,* then pour off the acid and wash the precipitate with warm water until it is completely freed from salt of ammonia; after which, it may be dried over a gentle fire.

Platina Sponge.—This is obtained by dissolving the metal in fillings in a mixture of one part nitric and two parts muriatic acid, diluting the solution with an equal quantity of water and precipitating the platina by means of aqua ammonia, which is afterwards separated in the form of a yellow powder, by filtering through paper. This, on being exposed to a red heat, will leave fine platinum in the form of a dark lead-colored spongy mass.

Purple Powder of Cassius.—**R** No. 1. This is a compound of gold and tin, and according to Thénard, is made by dissolving the gold in a mixture of one part muriatic and two parts nitric acid, diluting the solution with water, filtering and diluting again with a very large quantity of water. The tin is dissolved in *aqua regia*, composed of one part nitric acid, two parts water, and to every pint, add one hundred and thirty grains of muriate of soda. The tin should be pure and added to the acid in small pieces, waiting for each one to be dissolved before putting in another. The operation should be conducted in a cool place, and very slowly. After it is finished, the solution is filtered, and about one hundred times its volume of water added to it.

The solution of gold is now placed in a glass vessel, and that of the tin added to it—drop by drop—stirring constantly with a glass rod, until the liquid assumes the color of port wine. When the precipitate settles to the bottom of the vessel, the liquid is poured off, and the precipitate washed and dried.

Purple Powder of Cassius.—**R** No. 2. Pure silver,

* If an excess of ammonia is added, the precipitate will be redissolved and a fulminating compound formed.

432 grs. ;* gold foil, 48 grs. ; pure tin foil, 36 grs. Put the gold and silver in a crucible, cover well with borax, and melt ; then add the tin, and pour the melted mass immediately in cold water, to granulate it. Collect the particles, and melt and granulate again, repeating the operation two or three times, covering the metal each time with borax, and raising the heat no higher than is necessary to melt it, as the tin would be burnt out with a greater heat. The object of melting so often, is to mix the metals thoroughly together ; and the vessel in which it is granulated should be wood or porcelain.

Put the metal in a porcelain evaporating dish, and add nitric acid to decompose the silver, which operation will be expedited by a gentle heat. Should the acid cease to act before the silver is all dissolved—which may be known by the fumes ceasing to rise—it should be poured off, and fresh acid added. When the silver is all decomposed, pour off the acid, leaving the precipitate behind. Put this, which is the purple cassius, in a deep glass vessel ; fill it with water, and stir with a glass rod. Let it stand until the sediment subsides ; then pour off the water, and add fresh,

* Pure silver may be obtained in the following manner : Dissolve the silver in a mixture of one part nitric acid and three parts water, in a glass or porcelain vessel. The action of the acid will be expedited by applying a gentle heat. If there should not be acid enough to decompose the silver, it may be poured off when the effervescence stops, and the fumes cease to rise, and fresh acid added. When the silver is all dissolved, filter the solution through a glass funnel, into a glass or porcelain vessel. Then add a large quantity of water. Now, add to the solution of silver, a strong solution of chloride of soda, (common salt,) in hot water, until it ceases to cause a white precipitate, which is the chloride of silver.

When this precipitate has subsided to the bottom of the vessel, pour off the liquid and add fresh water, repeating this operation until the water comes off pure, and free from metallic taste. Now, dry the chloride. This done, put into a crucible two and a half times its weight of carbonate of potassa, (salt of tartar, or pearl-ash.) Place the crucible in a strong fire ; and when the carbonate of potassa is melted, add the chloride of silver in small portions, using the precaution not to add too much at a time, as, in this case, an effervescence would take place, which would cause it to be ejected into the fire. When the chloride is all reduced, the silver will be found in the bottom of the crucible in a pure state. The heat should be great enough to melt the silver, so that it may run down to the bottom of the crucible. After cooling sufficiently to solidify the silver, the melted mass on top may be poured off, and the silver taken out and cleaned.

repeating the washing until the water is free from metallic taste. The purple cassius is now dried in an evaporating dish, and kept dry for use.

The nitric acid poured off contains the silver, and may be obtained in a metallic state, in the manner as described for obtaining pure silver.

Oxyd of Titanium.—This is found in nature—sometimes nearly pure, and sometimes combined with oxyd of iron. The principal ores are *sphene*, common and foliated; *rutile*, *iserine*, *menachanite*, and *octapelite*, or *pyramidal titanium ore*. The purest varieties should be selected for use.

Oxyd of Uranium.—The prepared article, as sold by chemists, contains about two parts of the metal, and three of the oxyd, in the form of a yellow powder. It is generally used as found in nature.

Oxyd of Manganese.—This occurs abundantly in nature, and is obtained from chemists in the form of a coarse black powder.

Oxyd of Silver.—This is made by dissolving silver in nitric acid, and precipitating the silver by adding potash or soda to the solution. The liquid is then poured off—the precipitate washed with water and dried.

Oxyd of Cobalt.—The preparation of this oxyd is attended with much trouble, and as the quantity used in the manufacture of teeth is so small, we do not deem it necessary to describe the process, and especially as it can be obtained from most chemists. There is a preparation made from the oxyd, superior to the oxyd itself for coloring teeth. It is called, in popular language, the ashes of cobalt, and is made by wrapping the oxyd in blue English laid paper, and burning it in a closed crucible. This gives a more desirable tint to the enamel of a tooth than the oxyd.

COMPOSITION AND PREPARATION OF BODY.

We shall give but four recipes for body, either of which, if properly worked, will produce good teeth.

No. 1.		No. 3.	
Delaware spar,	12 oz.*	Delaware spar,	12 oz.
Silex,	2 " 5 dwts.	Silex,	3 "
Kaolin,	7½ "	Kaolin,	18 dwts.
Titanium,	18 to 36 grs.	Titanium,	18 to 36 grs.
No. 2.		No. 4.	
Delaware spar,	12 oz.	Delaware spar,	16 oz.
Silex,	3 " 8 dwts.	Silex,	3½ "
Kaolin,	8 "	Kaolin,	½ "
Baltimore clay,	4 "	Titanium,	20 to 60 grs.
Titanium,	18 to 36 grs.		

Put the titanium in a large mortar and grind until it is reduced to an impalpable powder, then add the silex and grind from one to three hours, or until there shall be no perceptible grit; now add the kaolin and grind from thirty minutes to an hour and a half, and lastly add the spar, little by little, and grind from forty to sixty minutes. All the ingredients should not be ground equally fine, as the translucency of the teeth is increased by having some coarser than the rest.

The materials may be ground dry or in water. If the latter method is adopted, a sufficient quantity of water should, from time to time, be added, to form a batter of the consistence of cream, and after the grinding is completed it may be poured on a clean slab made of plaster of paris, and as soon as it acquires the consistence of stiff dough, it may be removed, and after having been beat for twenty or thirty

* All the ingredients should be weighed with Troy weights.

minutes on a marble slab, put away in an earthen jar for use. When the ingredients are ground dry, they may be mixed, a small quantity at a time, as they are needed for use. Many prefer having the materials ground in this way.

COMPOSITION AND PREPARATION OF ENAMEL.

Any of the following recipes will produce a good enamel, and among them will be found nearly every shade of color and tint required, but others may be obtained, if desired, by adding other coloring ingredients. The author, however, has not found it necessary to do so. The oxyds should be reduced to an impalpable powder, and thoroughly incorporated with the enamel paste.

Grayish Blue Enamel.

No. 1.

Boston spar, 2 oz.
Platina sponge, $\frac{1}{4}$ gr.
Oxyd of gold, $\frac{1}{2}$ gr.

No. 2.

Boston spar, 2 oz.
Platina sponge, $\frac{1}{2}$ gr.
Oxyd of gold, $\frac{1}{2}$ gr.

No. 2.

Boston spar, 2 oz.
 Titanium coloring, 2 dwts.
 Platina coloring, $2\frac{1}{2}$ grs.

No. 3.

Boston spar, 2 oz.
 Platina coloring, 1 dwt. 12 grs.
 Titanium coloring, 3 grs.

No. 3.

Boston spar, 2 oz.
 Titanium coloring, 3 dwts.
 Platina coloring, 3 grs.

* The proportion of coloring ingredients may be increased or diminished, according to the color wanted. A sufficient variety of shades for most cases, will be obtained from the recipes which we have given.

The foregoing are ground separately until the coloring ingredients are thoroughly incorporated with the spar. By grinding the spar too fine, the life-like appearance and beauty of the enamel will be destroyed.

The manner of preparing the coloring ingredients for the following recipe, is as follows :

Platina Coloring.—Platina sponge, 1 dwt., 12 grs.; Boston spar, 1 oz. $2\frac{1}{2}$ dwts., mix and grind very fine.

Gold Mixture.—Dissolve eight grains, pure gold, in *aqua regia*, then stir in twelve and a half dwts. very finely ground spar. When nearly dry, form it into a ball, and fuse it on a slide in a furnace. After which, pulverize it coarsely and keep it for use.

Grayish Blue Enamel.

No. 1.

Boston spar, 2 oz.
Prepared platina
sponge, 2 dwts.
Gold Mixture, 4 grs.

Yellow Enamel.

No. 1.

Boston spar, 2 oz.
Titanium, 16 grs.
Prepared platina
sponge, 8 grs.
Gold mixture, 2 dwts. 10 grs.

For the yellow enamel, first grind the titanium and platina sponge very fine, then add the gold mixture, which should also be ground fine; after which add the spar and grind until the coloring ingredients are thoroughly incorporated with it.*

Gum enamel is made with a frit, colored either with metallic gold in a state of minute division, its oxyd, or purple cassius and spar. Besides the coloring ingredients, gum enamel frit is composed of a flux, made especially for the purpose, and spar. We shall first describe the manner of making the flux.

* In all but one of the foregoing recipes, the Boston spar is mentioned, and for the reason that it fuses at a somewhat lower temperature than the Delaware, which the author has designated as the kind to be used in the recipes for the body. There are two or three kinds of spar obtained near Philadelphia, very similar to the Delaware. Enamels made from any of the recipes here given may be used on any of the bodies.

Flux.—Sillex, 4 oz.; glass of borax,* 1 oz.; sal tartar, 1 oz.; mix and grind to an impalpable powder; then pack it in the bottom of a clean, light-colored crucible. Cover this with a piece of slide, previously fitted into the top, and lute with kaolin or clay. Now place the crucible in a strong anthracite fire, free from smoke, and let it remain until the mass is completely fused, which will require from an hour and a half to two hours and a half, depending on the strength of the fire.

When cold, break the crucible, and remove every particle from the flux; which, if it has not become stained by coloring matter in the crucible, will be a transparent glass. If any portion has become discolored, this should be broken off, and the remainder pulverized, and kept dry for use.†

Gum Frit, No. 1.—Metallic gold in a state of minute division or its oxyd, 16 grs.; flux, 175 grs.; spar, 700 grs.

Put the above in a mortar, and grind until it is reduced to an impalpable powder, which will require from five to eight hours constant labor, then pack it in a light colored crucible washed inside with a thin batter of very finely pulverized sillex, and outside with kaolin; now fit to the top of the crucible a piece of slab and lute it down with kaolin, place it near a fire, and when dry put it in a strong anthracite fire, free from smoke, in a furnace where it must remain until it is fused, which will require from an hour and a half to two hours, then remove it and when cold, break the crucible and grind off the sillex. This done, it may be broken and ground until it will pass through a sieve, No. 9 bolting cloth.

Gum Frit, No. 2.—Purple cassius, 8 grs.; flux, 175 grs.; spar, 700 grs. Reduce the purple cassius, in a mortar, to

* Glass of borax is made by putting the pure crystals in a clean light-colored crucible; then place the crucible in a fire free from smoke, and let it remain until the borax assumes a transparent glassy appearance. Now pour it on a clean marble slab, and when cold, pulverize and keep in a well stopped bottle to prevent it from absorbing the moisture from the air.

† Flint glass is sometimes used for a flux.

an impalpable powder, then add the flux, little by little, grinding each time, to a very fine powder. Now add the spar, a small quantity at a time, reducing each parcel to a very fine powder, and the whole to the utmost degree of fineness. To do this properly, will require from six to eight hours constant labor, and unless the mixing and levigation are conducted in a right manner the resulting color will be unsatisfactory.

After having reduced the mass to the proper fineness, select the whitest sand crucible that can be obtained, fit a piece of slide to the top, as a cover. Now cover the internal surface of the crucible with a paste made from finely pulverized quartz, putting it on with the finger. This done, pack the frit into it in a dry state, then put the cover on and lute tight with kaolin. Now put an external coating of quartz on the crucible ; then bury it in a strong anthracite fire, and let it remain until the contents are perfectly fused. The time required for this, will vary according to the size of the crucible and the strength of the fire. When the frit is completely fused, the crucible may be removed from the fire, and when cold, break it and remove every particle of foreign matter. Then pulverize until it will pass through a sieve of No. 9 bolting cloth.*

Gum Enamel.

No. 1		No. 2.	
Frit, No. 1,	3 dwts.	Frit, No. 2,	3 dwts.
Spar,	9 to 12 dwts.	Spar,	3 to 18 dwts.

The spar should be coarsely ground, in order to give the gum a granular appearance, and the quantity of frit may be increased or diminished until the right color is produced. It should, therefore, be tried on test pieces of body before being applied to a practical piece. Frit made at different

* For a number of the foregoing recipes, the author is indebted to the liberality of several professional friends, whose skill in this department of dentistry is unsurpassed.

times will produce different results. The gum enamel, No. 2, is designed particularly for body No. 4, and enamel No. 4, but may be used on any of the other bodies, and with any of the other enamels.

Having enumerated the materials which enter into the composition of the body, enamel and gum, and described the manner of preparing and mixing them for use, we shall proceed to notice the method of making and mounting the teeth. We shall begin by describing the manner of obtaining an antagonizing model for a set for the upper jaw, and of making the matrix for moulding the body preparatory to carving the teeth.

ANTAGONIZING MODEL FOR AN UPPER SET OF BLOCK TEETH.

The method of procedure for obtaining an antagonizing model for block teeth is similar to the one described in a preceding chapter, and one made for this purpose will answer for any other kind of dental substitute. A rim of softened yellow wax, about half an inch thick, is placed upon the lower or convex surface of the plate. This is then adjusted in the mouth, and the patient requested to close his teeth in the wax with sufficient force to make an indentation in it, an eighth of an inch deep. The piece is now taken from the mouth, the wax carefully removed, and another rim, corresponding in width to the length required for the artificial teeth, fitted to the plate, which is again placed in the mouth, and the patient requested to close his teeth gently upon the wax. If all do not touch the lower edge of it at the same instant, it should be trimmed off until they do. The exterior surface of the wax should be also cut away until it describes the proper arch for the buccal and labial surfaces of the artificial teeth and restores to the lips and cheeks their natural contour. This done, the patient is again requested to close his teeth upon the edge of the wax with just sufficient force to leave the imprint of each tooth.

The plate is now taken from the mouth, laid aside, and the wax first employed placed upon a piece of pasteboard or paper, with the side in which the teeth were partially imbedded, upwards. The exposed portion and indentations are smeared with oil. A batter of plaster of paris is next poured on it, filling the impressions made by the teeth, and running down an inch and a half behind it on the paper, and the whole raised to a level of half an inch above the wax. As soon as the plaster has consolidated sufficiently, the edges should be trimmed off, and a crucial groove, or two or three conical depressions made in the lower surface behind the wax, which may now be softened and carefully removed, using the precaution not to break the ends of the teeth. This done, the model is placed upon a piece of paper with the teeth upwards, and the rim of wax last used, still attached to the plate, is adjusted to the teeth in such a manner that the point of each shall enter the imprint made by the natural organs the last time they were closed against it. The upper surface of the plate and model having been previously smeared with oil, batter of plaster of paris is poured on the two for the formation of the other part of the antagonist. When the plaster has congealed sufficiently, the two pieces are separated, and the plate and wax carefully removed, to be used for the formation of the matrix, in which to mould the body preparatory to carving.

MANNER OF MAKING A MATRIX FOR MOULDING THE BODY PREPARATORY TO CARVING THE TEETH.

Having obtained an antagonizing model, the inside of the wax is cut away until it presents the appearance represented in Fig. 225. It is left a little thicker than the artificial teeth will be, allowance having been made for shrinkage in the baking and also for the removal of a small portion in carving, especially from the part from which the incisors and cuspids will be formed. The plate and wax are now

returned to the upper part of the antagonizing model, and the exposed surfaces of both smeared with oil; then a thick

FIG. 225.

FIG. 226.

FIG. 227.

FIG. 228.

batter of plaster of paris is poured on in the manner as described for making the upper part of the antagonizing model. As soon as the plaster has hardened sufficiently, the edges are trimmed to the wax, the matrix separated, and the lower part of the antagonizing model applied. Vertical lines are now made across the wax, to indicate the width required for the artificial teeth. See Fig. 226. This done, the antagonizing part of the model is removed the lower part of the matrix applied and the lines in the wax continued across the edge of it, to serve as a guide for marking the

width of the teeth preparatory to carving. See Fig. 227.

The two parts are again separated and the plaster cut away from the surface in contact with the wax of the lower piece, forming an open space between it and the edge of the wax, equal in width to about one-tenth or twelfth of that of the latter. The matrix will now present the appearance, when the two parts are put together, represented in Fig. 227. The object of this space is to provide for the shrinkage in the length of the teeth, consequently its width should correspond with the amount which the paste for the body shrinks in baking. Body made from the first recipe shrinks a little more than one made from the second, and one from this a little more than one from the third.

Having proceeded thus far, the wax may be removed, and a coat of varnish applied to each part of the matrix. The appearance of the two pieces when put together is shown in Fig. 228. The antagonizing model and matrix, as will be perceived from the foregoing description, consist of but three pieces. By this simple contrivance, the artist will be able to adapt the coronal extremities of the artificial teeth to the opposing natural organs, with the most perfect accuracy, as he can at any moment remove the lower part of the matrix and apply the antagonizing part of the model to his work.

Some dentists are in the habit of first carving the teeth in wax, and making the matrix to consist of five pieces; one upper and one lower, and three for the sides and front. In this the teeth are roughly moulded. But they afterwards require trimming, and it is quite as easy, and much more expeditious to carve them from the porcelain paste in the first instance. One who is skilled in the business, can carve a double set, after having moulded the body in matrices like the one we have described, in an hour and a half or two hours.

MOULDING AND CARVING.

A block for an entire set of teeth for the upper or lower jaw, shrinks so much in baking, as not only to destroy its adaptation to the plate, but also the proper relationship of the artificial to the natural teeth. But this difficulty may be measureably obviated by making three blocks, a central for the incisors and cuspids, and two lateral for the bicuspid and molars. Some are in the habit of making four, but with a good body, three are all that are required. The central should be made first.

If the composition for the body has been ground in a dry state, as much as may be needed at any one time, may be put in a mortar, and a sufficient quantity of clean water poured on to form it into a thick batter, stirring it until thoroughly mixed. It should then be poured on a slab of plaster of paris, as before directed, for the absorption of the surplus water, and afterwards beat for a few minutes on a marble or porphyry slab. Thus prepared, the matrix, after having been well oiled, may be filled with the paste, patting it with the fingers for a minute or two, for the purpose of driving out the confined air.

As soon as the water has evaporated sufficiently, the paste protruding from the matrix, may be trimmed off, the lower part of the mould loosened, but kept in place, and the width of the incisors and cuspidati marked with the point of a small carving knife upon the body, the notches across the edge of the lower part of the mould serving as a guide for this part of the operation. The teeth, however, should be a little wider than the spaces between the notches or marks on the matrix, so that each cuspid will occupy one-third of the space indicated for the first bicuspid, this being about the amount which the front or central block will shrink in baking.

After marking the width, the outline of the labial surfaces may be traced, and the carving commenced, copying

nature as closely as possible. The teeth may be separated by drawing a thread, held in a small bow, between them. The antagonizing part of the mould may be applied from time to time, to enable the artist to determine the amount required to be taken from the palatine surfaces. In conducting this part of the work, a great deal of tact is required, as the slightest touch, or accident, will break the block; the body, in this state, being exceedingly tender and brittle. If it should, at any time, become too dry, it may be moistened by applying a little water with the point of the carving-knife, or a small camel's-hair pencil. The portion back of the cuspid teeth, is, of course, cut off, and may be put with the body not used.

Having completed the front block, it may be loosened from the plate, by gently tapping the part of the matrix to which it is attached, and then removed and placed upon pulverized silex, on a slide. This done, the matrix may be refilled with paste, and the side blocks carved, making the first bicuspids to occupy about one-third of the spaces marked on the matrix for the cuspids, and these, in like manner, are removed and placed near the central block, on the slide.

The only instruments required for carving are two or three small knives shaped something like the blade of a thumb lancet, but more pointed and smaller.

CRUCING, OR BISCUITING.

As soon as the blocks have become thoroughly dry, they may be put in the muffle of a furnace, previously heated, and subjected to a bright red heat, which will be sufficient to agglutinate the particles of the composition, but not to vitrify the body. This is called *crucing*, or *biscuiting*, and is sometimes done in a charcoal fire, in a small open furnace, the blocks, in this case, having been first placed on a little pulverized silex, in a crucible. But it is most readily effected in a muffle furnace.

If the carving has been roughly executed, the shape of

the teeth may be easily altered, and any rough places removed after the blocks have been cooled. They can now be handled without incurring much risk of breaking.

INSERTION OF THE PLATINA PINS.

FIG. 229.

Several methods of attaching blocks to a plate have been adopted, but the one which affords the greatest permanence and stability to the work, consists in soldering a band to platina pins inserted in the blocks behind the teeth, and afterwards to the plate. These pins are sometimes put in before the blocks are cruiced, but as the teeth are so exceedingly frail at this time, it is better to defer it until they have been subjected to this process. The manner of inserting them is very simple, and consists in drilling two small holes in the block behind each tooth, immersing the block suddenly in water, and inserting a pin, flattened at the end, in each hole. The space around them should be filled with the composition of the body mixed with water to about the consistence of thin cream. This may be applied with a small camel's-hair pencil, or with the point of the carving-knife. The pins should pass from half to two-thirds of the way through the block, and be about an eighth of an inch apart, one placed above the other. The blocks for a set for the upper jaw are represented in Fig. 229.

ENAMELING.

The enamel, when applied, should be of the consistence of cream, and if the teeth are to have a uniform color, it will only be necessary to use two kinds, one for the teeth and one for the gum. But in the majority of cases three

kinds are needed, a grayish blue for the lower part of the crowns, yellowish near the gum, and rose red for the gum. The teeth should be well cleaned before the enamel is put on. The gum-color should be applied first, then the yellow, and lastly the grayish blue, and the best method of putting it on is with a small camel's-hair brush. It should be of uniform thickness and come down a little below the ends of the incisors and cuspids, so as to give them the translucency peculiar to the natural teeth. A thin coating may also be applied to the grinding surfaces of the molars and bicuspid. It is not required on the palatine surfaces. In applying the gum-color, care should be taken to prevent it from coming down on the teeth, and at the same time to have it form a well defined edge. The grayish blue should overlap the yellow, blending the two tints in such a manner as to render it impossible to tell where the one begins or the other terminates.

The enamel having been applied, the blocks are carefully placed on a bed of silex on the slide, and when perfectly dry, put in the furnace.

FIRING AND BAKING.

This is usually done in a small muffle furnace, like the one represented in Fig. 230, though some dentists have a furnace constructed somewhat differently. A clear, strong fire, made of the hardest anthracite coal, is required for baking the blocks. It is first kindled with charcoal, and, after this has become thoroughly ignited, the anthracite is added, a little at a time, until the furnace is full. As the muffle, at the high temperature required for fusing the blocks, and under the weight of the coal above, is liable to sink down in the centre, it should be supported with a rest underneath, made of fire-brick clay. The anthracite coal, after it has settled and become thoroughly ignited, should be two or three inches deep on the top of the muffle, and the opening through which the fuel is introduced, closed.

Thus heated, the slide may be carefully introduced into the muffle of the furnace, the opening closed, and the door luted with fire clay. Some dentists use a test piece, consisting of a small piece of the paste used for the body, with a little enamel on one side of it, fixed to the end of a platina

FIG. 230.

wire, projecting from the inner extremity of a plug made of fire clay, and fitting a hole in the centre of the door of the muffle. By withdrawing this, the progress of the baking can be ascertained. But the use of it is not necessary, especially to one experienced in this business. Most persons are in the habit of opening the door of the muffle, and partially withdrawing the slide, as it is thought the blocks have baked sufficiently. When the enamel has become fused, and run smoothly over the surfaces to which it was applied,

FIG. 230. A muffle furnace; *a* Collar for the smoke-pipe; *b* the opening through which the fuel is introduced; *c* The muffle door; *d* The ash-pit door; *e* Stopper for the opening *b*; *f* Stopper for closing the opening to the muffle; *g* Stopper for the opening to the ash-pit; *h* muffle; *i* Stopper with platina wire and test; *j* Slide.

the process has been carried far enough. The upper stopper may now be removed, the draft of air cut off from the fire by closing the door to the ash-pit, and the furnace permitted to cool. When the combustion has ceased, and the temperature become so much reduced as to permit of the introduction of the hand into the muffle, the slide may be removed. If it is taken out before the furnace has cooled, the teeth will be very liable to crack under the blow-pipe.

FITTING AND ATTACHING THE BLOCKS TO THE PLATE.

The adaptation of the blocks to the base is, often, more or less impaired by the shrinkage which takes place in baking, and as it is important that they should fit with the nicest accuracy, it frequently becomes necessary to grind them before attaching them to the plate. The blocks should also be fitted to each other so perfectly, by grinding, as to render the line of union scarcely perceptible.

But having accomplished this part of the operation, and antagonized the blocks properly with the opposing teeth, they are retained in place with a rim of softened beeswax, applied to the labial and buccal surfaces, and outer edge of the base; the plate behind the blocks are then smeared with oil, and a batter of plaster of paris poured on, filling the arch, and covering the coronal extremities of the teeth. When this has hardened, the wax may be removed and the blocks taken from and applied to the base without disturbing their proper relationship. A strip of gold, a little thinner than that used for the base, about an eighth of an inch wide, and long enough to extend from the posterior palatine angle of the hindmost block on one side, around to the same point on the other. This should be slightly grooved, and accurately fitted to the plate along the outer edge of the blocks, with the grooved side towards them. This done, the plate may be marked, with a sharp pointed steel instrument, on the outside of this rim. The plaster and blocks

may now be removed, the strip of gold confined in its place by wrapping the plate with fine iron wire. It is then soldered at three or four different points, and afterwards all the way around to the plate.

The blocks may now be separated from the plaster, adjusted to the plate, and held in place partly by the rim just soldered to it, and partly by a rim of wax placed against their buccal and labial surfaces. The next thing to be done, is to apply a strip of gold from a quarter to three-eighths of an inch in width, and of the thickness of the plate, to the palatine surface of each block. A pattern for each of these linings is first made by applying sheet lead or tin to the block, which as it is pressed against it, is perforated by the platina pins. It is then trimmed to the proper size, and fitted accurately to the base. This is placed upon gold plate, and a piece of the same size and shape cut from it. The perforations in the pattern indicate the points at which the holes are to be punched through the plate. When these are made, it is applied and fitted tightly to the block, and the platina pins bent a little to one side to hold it firmly in place. These are then cut or filed off nearly up to the plate, the block returned to its place on the base, to which the lining should be made to fit with the most perfect accuracy, as well, also, as to the end of the lining of the adjoining block.

All the linings having been applied and the blocks adjusted to the base, a rim of wax may be put on the inside to keep the teeth in place while the outer rim is removed. The piece may now be put in plaster or a mixture of equal parts of plaster and fine sand, or coarsely pulverized quartz or asbestos; this done, a mixture of finely ground borax and water is applied along the line of connection between the linings of the three blocks, the linings and plate and the posterior extremity of the lining of each block and the outer rim of gold, as well as around each platina pin; to all of which places solder is applied. The work is now ready for soldering, and as this process has been described

in another place, it is not necessary to repeat what has already been said upon the subject. The process of finishing is also the same as that for a set of single teeth mounted upon plate.

FIG. 231.

FIG. 332.

The above cuts represent a front and palatine view of a set of block teeth mounted on a metallic base for the upper jaw. The rim on the outside around the upper edge of the block is not always put on, but it adds very much to the strength and beauty of the piece, and also to its cleanliness, if fitted up tightly, as it always should be, to the blocks.

There are two other methods of attaching blocks to a plate. One consists in making vertical holes through the blocks, one for each tooth after they have been cruced. A gold pin is passed through each tooth and riveted on the upper side of the plate; or, first soldered to the plate, and riveted on the grinding surfaces of the molars and bicuspids and the palatine surfaces of the incisors and cuspidati. The other method consists in soldering pins to the plate which pass half or two-thirds of the way through the teeth. But, according to the observations and experience of the author, the first is the most substantial method, and, therefore, we have not thought it necessary to give a detailed description of either of the others.

In making a double set of block teeth, the two matrices are made one with the upper and the other with the lower parts of the antagonizing model, made with two rims of wax, one representing the upper and the other the lower

teeth. The lines marked on the wax to indicate the width of the teeth are so arranged as to represent the relationship which the upper and lower teeth sustain to each other when the jaws are closed.

NOTE.—The originals of nearly all the illustrations in the foregoing chapter were made for the author by Dr. M. D. French, formerly a student of his, and for which courtesy he takes pleasure in acknowledging his indebtedness.

CHAPTER EIGHTEENTH.

SINGLE PORCELAIN TEETH MOUNTED ON A METALLIC BASE, WITH CONTINUOUS ARTIFICIAL GUMS.

SINCE the publication of the fifth edition of this work, the above method of mounting artificial teeth has been adopted extensively by the profession in most of the principal cities in the United States, and to some extent in Europe. It was introduced almost simultaneously by Drs. John Allen and W. H. Hunter, both of Cincinnati, Ohio, in 1851, each claiming priority of discovery. The former, however, secured to himself the exclusive benefit of it by letters patent. But the idea of uniting porcelain teeth to a metallic base by means of a fusible silicious composition, originated in France, where the method has, to some extent, been practiced since 1820. The composition employed there, however, judging from the specimens which the author has in his possession, cannot be used in connection with porcelain teeth containing as large a proportion of feldspar as those manufactured in this country. The credit of the discovery of such a composition belongs to Drs. Hunter and Allen.

It was thought when this method of mounting artificial teeth was first adopted, that the springing of the plate in the act of mastication would cause the gum to crack and scale off, and while this does occur in a large proportion of the cases, the injury is usually easily repaired by replacing the loss with fresh composition and fusing it to the fractured edges of the remaining portions, and to the plate. For beauty of appearance and cleanliness, it is unsurpassed by any other description of dental substitute.

By uniting the teeth to each other, near their base, and

to the plate, the cleanliness of the substitute is more perfectly secured, as all the openings beneath and around them are completely closed, excluding the secretions of the mouth and particles of alimentary substances, which, by finding lodgment in these places, soon become putrid, and impart to the breath an offensive odor. In this respect, they are superior to the most perfectly mounted block teeth, and the labor of putting up a set of the former can be performed in half the time required for making and mounting a set of the latter. The gum is continuous, without seam or crack, from one side to the other; and a person who can mount single teeth well, can acquire a knowledge of this method, with proper instruction, in two or three days.

Two compounds are employed: the first, is termed the *base* or *body*, as this constitutes the principal part of the cement and is used for filling in between the teeth and building up the gum on the plate, the other is termed *gum-enamel*. The materials employed by Dr. Hunter, in the composition of his compound are, sillex, fused spar, calcined borax, caustic potash and asbestos. The sillex and spar should be of the clearest and best quality, and ground very fine. The asbestos should be freed from talc and other foreign substances, and reduced to a fine powder. He gives the following formulas:

“*Base*.—Take flux*, 1 oz.; asbestos 2 oz.; grind together very finely, completely intermixing. Add granulated body,† 1½ oz.; and mix with a spatula to prevent grinding the granules of body any finer.

* The flux used by Dr. Hunter is composed of sillex, 8 oz.; calcined borax, 4 oz.; caustic potash, 1 oz. The potassa is first ground fine in a wedgewood mortar, and the other materials gradually added until they are thoroughly mixed. “Line a Hessian crock (as white as can be got) with pure kaolin, fill with the mass, and lute on a cover of a piece of fire-clay slab, with the same. Expose to a clear strong fire in a furnace with coak fuel, for about half an hour or until it is fused into a transparent glass, which should be clear and free from stain of any kind. This is broken and ground until it will pass through a bolting sieve.

† This may be made of hard porcelain, fine China or wedgewood, but Dr. Hunter uses spar, 3 oz.; sillex, 1½ oz.; kaolin, ½ oz.; completely fused. “Break and grind so that it will pass through a wire sieve No. 50, and again sift off the fine particles which pass through No. 10 bolting cloth,” which leaves it in grains about the size of the finest gunpowder.

Gum Enamels.—No. 1. Flux 1 oz.; fused spar, 1 oz.; English rose, 40 grains. Grind the English rose extremely fine in a mortar, and gradually add the flux and then the fused spar, grinding until the ingredients are thoroughly incorporated. Cut down a large Hessian crucible so that it will slide into the muffle of a furnace, line with silex and kaolin each one part, put in the material and draw up the heat on it in a muffle to the point of *vitrification*, not *fusion*, and withdraw from the muffle. The result will be a red cake of enamel which will easily leave the crucible, which, after removing any adhering kaolin, is to be broken down and ground tolerably fine. It may now be tested and then (if of too strong a color) tempered by the addition of covering. This is the gum which flows at the lowest heat, and is never used when it is expected to solder.

“No. 2. Flux, 1 oz.; fused spar, 2 oz.; English rose, 60 grains. Treat the same as No. 1. This is a gum intermediate, and is used upon platina plates.

“No. 3. Flux, 1 oz.; fused spar, 3 oz.; English rose, 80 grains. Treat as the above. The gum is used in making pieces intended to be soldered on, either in full arches or in the sections known as *block work*. It is not necessary to grind very fine in preparing the above formulas for application.

“*Covering.*—What is termed covering, is the same as the formulas for gums, *minus* the English rose, and is made without any coloring whatever when it is used for tempering the above gums which are too highly colored, and which may be done by adding, according to circumstances, from 1 part of covering to 2 of gum, 3 of covering to 1 of gum, thus procuring the desired shade. When it is to be used for covering the base prior to applying the gum, it may be colored with titanium using from two to five grains to the ounce.

“*Investient.*—Take two measures of white quartz sand, mix with one measure of plaster of paris, mixing with just

enough water to make the mass plastic, and apply quickly. The slab on which the piece is set should be saturated with water to keep the material from setting too soon, and that it may unite with it.

“*Memoranda.*—In preparing material, always grind dry, and the most scrupulous cleanliness should attend all of the manipulations. In all cases where heat is applied to an article in this system, it should be raised gradually from the bottom of the muffle, and never run into a heat. Where it is desired to lengthen any of the teeth, either incisors or masticators, or to mend a broken tooth, it may be done with *covering*, properly colored with platina, cobalt or titanium.

“In preparing a piece of work, wash it with great care, using a stiff brush and pulverized pumice-stone. Bake over a slow fire to expel all moisture, and wash again, when it will be ready for any new application of the enamel. Absorption, occurring after a case has been some time worn, by allowing the jaws to close nearer, causes the lower jaw to come forward and drive the upper set out of the mouth. By putting the covering on the grinding surface of the back teeth in sufficient quantities to make up the desired length, the coaptation of the denture will be restored, and with it the original usefulness.

“Any alloy, containing copper or silver, should not be used for solder or plate, if it is intended to fuse a gum over the lingual side of the teeth, as it will surely stain the gum. Simple platina backs alone, do not possess the requisite stiffness, and should always be covered on platina with the enamel, and on gold with another gold back. In backing the teeth, lap the backs or neatly join them up as far as the lower pin, in the tooth, and higher if admissible, and in soldering be sure to have the joint so made *perfectly soldered.*”

The composition originally employed by Dr. Allen, for the case consists of silix, 2 oz.; flint gloss, 1 oz.; borax, 1 oz.; wedgewood, $1\frac{1}{2}$ oz.; asbestos, 2 drachms; feldspar, 2

drachms; kaolin, 1 drachm; intermixed or underlaid with scraps of gold or platina. For the enamel, he employs feldspar, $\frac{1}{2}$ oz; white glass, 1 oz; and oxyd of gold, $1\frac{1}{2}$ grs.; which gives it the gum color. Dr. A. we believe now uses a somewhat different and better formula.

Since the publication of the sixth edition of this work, great improvements have been made in the composition and preparation both of the body and gum enamel, which are furnished by the manufacturers and may be obtained at many of the dentists' furnishing establishments at a very moderate price.

The metals employed for the base in this method of mounting artificial teeth, are, platina or pure palladium. The common commercial article of palladium is not pure; it contains about fifty per cent. silver. Platina, alloyed with pure gold may also be used.

In mounting a set of artificial teeth with the continuous gum, a plate is first struck up with the outer edge either turned up or a rim soldered on in the manner as described in a preceding chapter. The teeth are then selected, arranged on wax to the plate, the backings or linings put on, and united to the plate as in the ordinary way of mounting. The piece is now tried in the mouth and if the teeth were not antagonized properly on the model, each one is adjusted by pressing it slightly outward or inward as the case may require to give it an equal bearing upon the opposing teeth. This readjusting of the teeth may not often be necessary, but it is a precaution which it is well to observe, lest the mouth may not have been closed naturally at the time the antagonizing model was made.

Having proceeded thus far, the silicious compound, which flows at a lower heat than is required to fuse the teeth, is placed upon the plate and teeth in such a manner as to fill up all the interstices between and around their base, and then carved to represent the gums. This done, the cement is thoroughly dried, and the piece put on a slide with the coronal ends of the teeth downwards and imbedded to the

depth of about a quarter of an inch in a thick batter of plaster and asbestos, filling, after this has set, the upper and concave surface of the plate with the same composition.

After this has become dry, the slide is placed in a heated muffle and subjected to a heat sufficiently high to fuse the compound—say twenty-two hundred and fifty degrees. It is then withdrawn, cooled, and if the baking has caused no defects, gum-enamel is put on as in block-work, and when dry, the piece is put back in the furnace and this last composition fused as before. If defects occur in the first baking, they are repaired by filling up the cracks with more of the body or base, previous to putting on the gum-enamel. The enamel is sometimes put on before the first baking. If in baking, the composition leaves the plate, the piece may be put in the furnace a second time, but with the plate downwards, when, as soon as the compound fuses, it will at once come back to and unite with the plate. Great care is necessary in baking. If the piece is subjected to too much or to too little heat, it will be more or less defective, and the exact amount required can only be determined by one who has had some experience in this part of the operation.

In mounting teeth with the continuous gum it is necessary to rim the plate or to turn up the outer edge, to give thickness to the cement where it terminates upon the base. This stiffens the plate, and diminishes its liability to spring or the compound to crack and scale off. Additional stiffness may also be given to it, while at the same time the entire piece will be greatly strengthened, by soldering a band, extending all the way round, to the inside of the backings of the teeth, previously to putting on the compound, which may be thinly covered with it and gum-enamel, thus completely concealing it from view.

In constructing a dental substitute for the lower jaw, upon this principle, the plate, instead of being rimmed or turned up, should have a half round wire soldered to the upper surface of the edge all the way round, both on the buccal and lingual sides.

CHAPTER NINETEENTH.

CHEOPLASTIC METHOD OF MOUNTING ARTIFICIAL TEETH.

AMONG the peculiar advantages claimed for the Cheoplastic over the other methods now practiced, of mounting artificial teeth, are perfect accuracy of adaptation of the base to the plaster model—metallic castings not being used in this process—and greater practical usefulness and durability. It can also be done in less time, and the material used for the base in this process is less expensive—it being an alloy, the precise composition of which we have never taken pains to ascertain, as it can be obtained from the manufacturer, and at most of the dental depots, of a better quality, we presume, and at a lower price than it can be made for in small quantities. It is, however, composed principally of tin, silver and bismuth, with a small trace of antimony.* The alloy imparts no taste whatever to the mouth, and its purity, so far as its capability of resisting the action of the secretions of the buccal cavity is concerned, is said to be fully equal to that of eighteen carat gold. The lustre of it, after being worn some weeks, becomes slightly dimmed, but is immediately restored by placing it in a strong solution of caustic potash. This is the only change we have ever observed, and we have seen it after having been worn in the mouth nearly two years.

This method of mounting teeth has only been practiced

*As the right to manufacture the alloy, as well as the entire process, has been secured to the inventor, Dr. A. A. Blandy, by letters patent, the exact composition may be seen in the specification which accompanied his application for the patent.

since the fall of 1855, that is, with the above mentioned alloy, and it was not made known to the profession generally until February, 1857. Since this time, it has been adopted and practiced by nearly three hundred dentists, and among the number are many of the most skillful and respectable practitioners in the United States. Thus far we believe it has fully realized the expectations of its most zealous advocates, and judging from the testimony of others, as well as from results which have come under our own observation, the use of it seems likely, in a very short time, to become general.

FIG. 233.

In mounting artificial teeth by the Cheoplastic process, the first thing to be attended to is, to take an impression of the mouth either with wax or plaster of paris. If it is desired to have a central chamber or cavity in the base, with a view to make it adhere more firmly to the parts against which it is to rest, one of the right size, depth and shape, is cut at the proper place in the impression, which, if of plaster, is varnished, then placed on a piece of pasteboard or paper,

and surrounded with soft putty, or any plastic substance, as dough or clay. A sheet iron or tin ring is then placed over it, (the lower edge slightly embedded in the putty,) large enough to leave a space of about a quarter of an inch all around between the two, except at the back part, where it should be an inch and a quarter at least, for the formation of an articulating surface for the two parts of the matrix, which may also be used for the antagonizing model. The ring should be about an inch or an inch and a quarter in depth. See Fig. 233.

The model is made of equal parts, by weight, of plaster of paris and finely pulverized spar, mixed with pure water until of the consistence of thin batter.* The impression and surface of the putty, as well as the inside of the ring being oiled, the mixture is poured in, stirring it with a camel's-hair pencil, until it is raised to a level with the upper edge of the ring. As soon as it becomes sufficiently hard, the ring and putty are removed, and the model carefully separated from the impression, which, when the alveolar border does not project, may be done without injury to either. Half a dozen or more models can often be taken from the same impression. When the alveolar ridge projects, it is sometimes necessary to cut away the outer part of the impression before the separation can be effected, but when this is done, care is necessary to prevent injuring the model. Having removed this from the impression, the portion designed for the formation of the chamber in the base may be altered, if desired, and made smoother before proceeding farther with the operation.

The next thing to be done is, to make an antagonizing model, and as the method of obtaining it for this process is different from any heretofore given, we subjoin a brief description of it. Two or three conical holes are made in the back part of the model for the proper adjustment of the

* Models made of the above composition are not as hard as when made wholly of plaster of paris, but they are sufficiently solid for all practical purposes. If desirable, their density may be increased by the use of Fuch's solution of glass.

antagonizing portion; a coating of varnish is applied to every part except that which is to be covered by the base for the artificial teeth. This part is now covered with a plate of thick tin foil, stiffened by the application of soft wax to the part within the arch. This may be a quarter or three-eighths of an inch thick, and when it has hardened, a rim of softened wax is placed along the alveolar border and trimmed down with a knife until its width shall be a little greater than the length required for the artificial teeth. Remove this and the stiffened tin foil plate together, place them in the mouth before the wax hardens, and if the rim is of the right width all round, request the patient to bite upon it, closing the lower jaw naturally, until a distinct imprint of all the lower teeth is made in it. See Fig. 234.

FIG. 234.

This done, the wax and plate are removed from the mouth, replaced on the model, and the antagonist made in the manner as described in a preceding chapter.

The portion of the model representing the alveolar ridge and roof of the mouth, after the antagonizing part, the wax and tin foil have been removed, is covered with a fresh plate of tin. This is accurately moulded to the various depressions

and prominences with the finger, and hard rolls of chamois leather cut nearly to a point at each end—such as are used for shading drawings, called *stumps*. See Fig. 235. One

FIG. 235.

or two extra strips of foil may be placed over the prominent parts of the alveolar ridge to secure sufficient thickness of metal at those points between the teeth and gums. A plate of sheet wax, rolled to the thirty-fifth or fortieth part of an inch in thickness, is put over the tin, covering only so much

FIG. 236.

of the cast as is to be occupied by the metallic base. This is carefully and accurately moulded to the tin plate, and then trimmed to the required size. See Fig. 236, showing model and wax plate separated.

The teeth are now selected and arranged upon the wax plate on the model. Gum teeth, either single or in blocks of two or three are preferable. As they are arranged upon the cast, the approximal sides are ground until the teeth or

FIG. 237.

blocks come together so perfectly at every point as to render the line of union scarcely perceptible. But the teeth used in this process are constructed differently from those designed for swaged plates. They are not provided with platina pins in their palatine surface, but have holes or dove-tail grooves

into which the metal runs, retaining them securely to the base. A section of single and block teeth designed for this process are represented in Fig. 237, with the metal. Plate teeth can be used and attached very securely by bending the platina pins until the ends come together. As it is not a matter of any importance whether the base of the teeth fit closely to the wax plate or not, it is rarely necessary to grind them here. It is only done when the teeth are too long.

Each tooth or block, after having been properly ground, is made fast to the wax plate by applying melted wax to the palatine surface, filling the holes or grooves, which runs down and unites with the plate beneath, from the point of an instrument constructed for the purpose, pre-

FIG. 238.

viously warmed in the flame of a spirit lamp. See Fig. 238. The antagonizing part of the model is applied from time to time, as the teeth are arranged, in order to insure accuracy of adjustment, and when the proper care is taken, it will seldom be necessary, if the bite of the lower teeth has been properly taken, to make any alteration in the

piece after it is put in the mouth, the holes or grooves of the teeth being filled—the amount of wax applied to the backs of the teeth is equal to the amount of metal required to unite them firmly to the base. This may be done by putting a narrow strip extending all the way round from the back tooth on one side, to the back tooth on the other; or it may be applied in small pieces, using the wax knife warm in either case, to unite it to the teeth and wax plate. Another strip is now applied along the upper edge, on the labial and buccal sides, filling the groove above the gum, and uniting it with the wax plate, with the instrument, Fig. 238, warmed sufficiently to melt the wax. This strip is long enough to pass behind the last tooth or block on each side, and unite, with the wax applied along the palatine surface. As metal is ultimately to take the place of wax, it is important that the exact quantity required be put on and every part made perfectly smooth. This may be done with the wax knife, while warm, and brushes like

FIG. 239.

those represented in Fig. 239. The largest is designed for pressing it down upon the model, and the smaller to smooth it between the teeth, and where the wax knife cannot be conveniently employed. The smoothing process may be facilitated by throwing the flame of a spirit lamp lightly over the wax with a blow-pipe having a very small aperture in the nozzle, slightly melting the surface and causing it to

flow. This gives it a beautifully polished appearance. In proportion as this part of the operation is neatly and skillfully executed, will the labor of finishing, after the metal has been applied, be lessened.

FIG. 240.

An upper set of single gum teeth, arranged on a wax plate and model, is represented in Fig. 240. Now, if there

FIG. 241

is any doubt with regard to the proper adjustment of the teeth, arising from fear that the bite of the lower teeth in

the rim of wax for the formation of the antagonizing part of the model was not natural, the piece may be tried in the mouth of the patient, and should any alteration be necessary, it is made before proceeding further with the work.

When single teeth without gums are used, the strip of wax in front and on each side is pressed between each two and scalloped out, giving it a festooned appearance like the natural gum, and leaving points between the teeth. A set thus prepared, is represented in Fig. 241, with wax made perfectly smooth between and around the teeth.

FIG. 242.

At this stage of the operation, the work is placed in the ring in which the model was made—the upper edge of the former projecting about a fourth of an inch above the summits of the teeth, as shown in Fig. 242. The exposed surfaces of the model and inside of the ring, are well oiled, and a mixture of plaster of paris and spar, in the before mentioned proportions, are now made into a thin batter, and poured on gradually, until the ring is filled, stirring as before directed, to drive out air bubbles, and

ensure a perfect cast. When the mixture becomes hard, the ring is removed, and the part of the matrix first made is tapped lightly with a small hammer or mallet until the one loosens a little from the other, when the two may be easily separated with the hands. This done, cut immediately, while the composition is comparatively soft, a groove or gate in the part of the matrix last made, which contains the teeth and wax plate, through which the melted alloy is

FIG. 243.

to be poured, and two vents, one on each side, see Fig. 243, with half of wax plate removed, showing ends of the teeth. These are made before the wax is removed, to prevent small pieces from falling in the matrix by the sides of the teeth. The wax is now removed as perfectly as possible, as the absorption of any small portions left in the matrix has a tendency to roughen it, and thus to prevent the metal from running as smoothly as it would otherwise do. After removing the wax, each part of the matrix is held over the flame of a tallow candle, until a slight coating of carbonaceous matter forms on it. The two parts are now put together and firmly united by passing an iron wire two or three times around it and made fast by twisting the ends tightly where they meet. The line of union is next luted with a mixture of plaster and spar, leaving the gate and vents open. This is necessary to prevent the metal from escap-

ing when poured, and even this does not always do it. Hence, additional means of security are sometimes employed. The simplest and perhaps the best, is to put the matrix, after wiring and luting, into a sheet iron or tin

FIG. 244.

box, (see Fig. 244,) partially filled with a thick batter of plaster and spar, with the gate and vents upwards, thoroughly imbedding it in the mixture.

Thus secured, the piece is put in a small gas sheet iron furnace, stove, kitchen range or bake oven and exposed to a bread baking heat, say from 300° to 400° Fh., for from three to five hours, or until every particle of moisture is driven from it. It is then placed in an upright position, the metal melted, and while at a temperature sufficiently high to make it assume a light blue color is poured quickly into the matrix. If it does not bubble, and comes up into the vents freely, the piece will come from the matrix in a perfect condition. If it bubbles it may be tapped several times lightly on a brick or some hard substance. When cold, the two parts of the matrix are separated, exposing one of the surfaces of the plate. If any part is found defective, now is the proper time to repair it. This is done with solders Nos.

1 and 2, prepared for the purpose,* muriate of zinc being used as a flux.† This latter is applied to the defective part on the end of a small piece of wood, previously dipped in the liquid muriate. A sufficient quantity of solder is now placed on the defective part and a small jet of flame from a spirit lamp is thrown lightly on it with a blow-pipe having a very small hole in the nozzle. As soon as the solder flows freely and smoothly the projection of the flame is immediately discontinued.

But when the process is properly conducted from the beginning up to this point the piece will come from the matrix perfect in all its parts, and when the metal fails to flow freely around the teeth and to cover perfectly the alveolar border and palatine arch, it is better to melt it from the matrix. with the flame of a spirit lamp projected upon it with a blow-pipe, and pouring a second time—using the precaution not to concentrate it too long on the teeth, as in this case there would be danger of cracking them. When this is done, the matrix is secured as in the first instance.

Before removing the piece from the part of the matrix last made, the cavity in the plate, if one has been formed, is made smooth with scrapers and polished with prepared chalk on a wheel brush revolved in a lathe. The remaining part of the matrix is now removed, and the edges of the plate properly rounded with a coarse file; the asperities of the exposed surfaces are removed with scrapers made for the purpose, and if necessary, the thickness of the palatine portion may be reduced. This done, these surfaces are rubbed first with coarse and afterwards with fine emery cloth, then washed in soap and water, with a hard brush, afterwards burnished and finished by polishing with chalk on a

* The above solders are furnished with the alloy used for the base. No. 1 is prepared for use by melting and pressing it, while hot, between two smooth flat surfaces. No. 2 is made into thin plate before using by passing through a rolling mill.

† This is made by dissolving pure zinc in muriatic acid until the acid can take up no more of the metal. This flux improves by age, and should not be used if possible to avoid it for three months.—*Book of Instructions for Mounting Teeth on the Cheoplastic Process.*

wheel brush as described above. The upper surface of the plate must not be scraped as the accuracy of its adaptation to the gums and palatine arch would be injured by it. It may be polished however with chalk on a wheel brush, but every other part ought to be finished in the neatest and most perfect manner. The polishing up to this point being completed, the piece is put in a strong solution of caustic potash, boiled for two or three minutes, then washed in pure water, wiped dry and finished by repolishing with chalk and the brush.

If the piece is to be gilded, it should be first put in the mouth and worn a few days, to ascertain if the adaptation is perfect, as any future alteration would deface it and render a second covering of gold necessary. The adjustment being correct, the piece is cleansed from the secretions of the mouth and all foreign matter by boiling again in a solution of caustic potash and washed in pure water; it is then polished with chalk, washed and wiped dry; it is then put in the "gilding solution," but during the deposition of the gold, it should be removed several times, burnished and polished to give solidity to the plating, and remedy any defect that may be discovered. After a sufficiently thick coating has been deposited, say from three to five dwts., it is finished as in the first instance, by burnishing and polishing.

The practical value of a piece is not enhanced in the slightest degree by gilding—the alloy being tasteless and not acted upon by the secretions of the mouth. Indeed, unless the deposit of gold is tolerably thick and perfect at every point, it is productive of injury. As a general rule, therefore, a piece may be said to be better without it than with it. For a description of the process of electro-plating, the reader is referred to works devoted especially to the subject.

In mounting a set of teeth for the lower jaw by the Cheoplastic process, the gate through which the metal is poured into the matrix should have two lateral branches—one on each side, to admit it more freely than one can be

made to do. The wax plate should also be thicker, to give sufficient strength and stability to the base, but in every other respect the method of procedure is almost precisely the same as that described for an upper set. For a partial lower set, say for the molars and bicuspsids on each side, the wax plate should be extended behind the remaining front teeth, and two or three thicknesses may be applied here to stiffen it sufficiently to prevent it from breaking or bending when pressure is made on the teeth of the base on each side.

FIG. 245.

In making an antagonizing model for an entire set of teeth, the wax plate of the model of the lower jaw is stiffened by the adjustment of a piece of iron wire about double the diameter of a medium sized knitting-needle,

bent to the curvature of the arch, and made fast to the inner edge of the plate, by being partially imbedded in it. The rim of wax is now arranged along the summit of the alveolar borders, and after being properly trimmed, the whole is taken from the model and put in the mouth. The upper plate and rim of wax is then adjusted and the bite of the mouth taken and the antagonizing model made in the manner as described for a full set of block teeth to be mounted on gold. See Fig. 245.

FIG. 246.

In Fig. 246 is represented a set of teeth in an antagonizing model, the upper and lower ready to be placed upon their respective models for the formation of matrices.

For partial sets of teeth the Cheoplastic process is peculiarly applicable, the perfect

accuracy of the adaptation of the base secures so firm an adhesion to the mouth as to render clasping to any of the remaining natural teeth almost always unnecessary. A single tooth or several teeth situated in different parts of the arch, can be replaced with the greatest ease, and they are so securely retained as to occasion no inconvenience or annoyance to the patient. The only precaution necessary to be observed in their construction, in addition to that of accuracy of adjustment and neatness of execution, is to thicken the projections of the wax plate between the remaining natural teeth sufficiently by adding melted wax, to prevent the liability of breaking. These portions, when very narrow, should be made double the thickness of the other parts of the plate. After having adjusted the artificial teeth, and made them fast to the wax plate, the teeth of the model are cut off before making the matrix, as it would be impossible to separate the two parts of it without breaking them.

A piece from which one or more teeth have been broken can be easily repaired. If any portion of the tooth remains it is removed, and the metal that united it to the base filed away. A new tooth is selected and ground until it fits the teeth accurately on each side of the aperture. The floor of the groove filed in the base is covered with a piece of wax of the thickness of that used for the plate; the tooth is then put in place, wax applied on the outside of the upper edge, filling the groove in the plate; it is next placed on the inside side, filling the hole or groove in the back of the tooth, designed for its attachment to the base. This is chiefly done with the wax knife, Fig. 238, made hot in the flame of a spirit lamp. The apex of a roll of wax about an inch and a half in length, of a conical shape, is united to the wax on the back part of the tooth. The apex should be a little more than an eighth, and the base half an inch in diameter. The latter should be half an inch above the summits of the teeth. A small stem of wax is united

to the wax on the outside of the tooth, with the free extremity half an inch above the tooth.

The sheet iron or tin ring employed in making the model is now filled about one-third full of plaster and spar, mixed with water, until about the consistence of batter, and the piece put immediately in it with the base downwards, pressing upon it sufficiently to imbed the concave surface. A thin mixture of the same composition is then poured on top, filling the ring and covering the summits of the teeth about a quarter of an inch. When hard, the ring is removed, and the projecting stems of wax withdrawn. The wax on each side of the tooth and between it and the base is melted out by throwing the flame of a spirit lamp with a blow-pipe into the gate behind the tooth and the vent in front.

The matrix thus formed is dried and made hot in a stove or furnace, as in the first instance. The alloy is then melted and poured into it through the gate behind the tooth, and if it comes up, filling the vent in front without bubbling, the piece will come from the matrix perfectly restored. When cold, the plaster and spar are broken from the teeth and the metal around the new tooth finished in the manner as previously described.

PART SEVENTH.

DISEASES AND DEFECTS OF THE PALATINE ORGANS.

PART SEVENTH.

DISEASES AND DEFECTS OF THE PALATINE ORGANS.

ALTHOUGH the treatment of the diseases of the palatine organs belong more properly to the province of general medicine than to the specialty to which the present treatise is chiefly devoted, yet, inasmuch as the surgeon dentist is often called upon to remedy the defects that sometimes result from them, it is important that he should have, at least, some general knowledge of the morbid phenomena liable to be developed in these parts. But in treating of these diseases, it is not the intention of the author to enter into a minute description of their pathology or therapeutical indications. His principal object is to notice the defects resulting either from the changes of structure to which they are liable to give rise, or from malformation, and to point out the means by which they are remedied.

The defects of the palatine organs may be divided into *accidental* and *congenital*. The first, as has been just intimated, are caused by a pathological change of structure. The second are the result of malformation or imperfect development of the parts. But from whatever cause they may be produced, their effects upon the voice, speech, mastication and deglutition are the same. These functions are all impaired by them, in proportion to their nature and extent. When they extend so far as to cause a complete division of the hard and soft structures, distinct utterance is wholly destroyed, and the acts of mastication and deglutition are greatly impaired and always performed with difficulty.

When the loss of substance is the result of disease, and extends so far as to establish a communication between the mouth and nasal fossæ, the defect can seldom be remedied in any other way than by means of an artificial obturator; and even when it is congenital, though the aid of surgery may very often be successfully invoked, the resources of art, in the majority of cases, will be required. When the defect is confined to the vault of the palate, and consists of a simple opening between the mouth and nasal cavities, these resources may always be successfully applied, and even when the loss of substance extends to the soft palate, and anterior part of the alveolar ridge, a mechanical appliance may be so constructed, as to restore, in a great degree, the functions dependent upon the presence and integrity of the natural parts.

CHAPTER FIRST.

DISEASES OF THE PALATE.

IN common with other parts of the body, the palate sometimes becomes the seat of various morbid phenomena, but the occurrence of disease here is generally the result of constitutional causes, such as certain depraved habits of body. It is perhaps, more frequently induced by secondary syphilis than any other cause, and when it is, its ravages are often truly deplorable. It may, however, result from the immoderate and protracted use of mercurial medicine, or from a scorbutic, cancerous, scrofulous or rickety diathesis of the general system. Among the diseases liable to attack the palate, are tumors, caries and necrosis of the bones, ulceration of the mucous membrane, and inflammation, elongation and ulceration of the uvula. In consulting writers on the diseases of the palate, the author has been able to find but few who have treated on them at much length, and for the information which he has been able to obtain upon the subject, except that which he has derived from his own limited observations, he is principally indebted to Jourdain and Boyer. The first of these authors has devoted, in the first volume of his Treatise on the Surgical Diseases of the Mouth, about one hundred and forty pages to the affections under consideration.

TUMORS OF THE PALATE.

Tumors of the palate are less frequent in their occurrence than morbid growths from the gums and alveolar processes, and they are as variable in their appearance and character

as are those which are developed from other parts of the mouth. Sometimes they originate from the mucous membrane, at other times from the periosteal tissue. Sometimes they are attached by a broad base ; at other times by a very narrow one. Some have a smooth surface, a whitish and pale red color, and a firm fleshy texture. These generally grow very slowly, and are seldom of a malignant character. Others have an uneven surface, are soft and vascular, of a purple color, and bleed from the slightest injury.

The last are of a more malignant nature, and frequently have a cancerous tendency. They are also more sensitive to the touch and more painful. The first are seldom attended with much pain, and are less dangerous. In forming a prognosis, therefore, it is necessary to distinguish between those which are simple, and those which are of a malignant or cancerous nature.

Tumors of the palate, as well as those of other parts of the mouth, are always productive of annoyance and inconvenience to the patient in proportion to their size and the malignancy of their character. They impede, and, sometimes, destroy the functions of mastication, and render those of speech and deglutition exceedingly difficult and imperfect.

A more minute description of tumors of the palate is deemed unnecessary, since that which has been given, in a preceding part of the work, of the morbid productions of the gums and alveolar processes, will, for the most part, be found as applicable to the one as to the other. But with regard to the peculiar pathological characteristics and nosological classification of the various kinds of tumors, it has constituted no part of the design of the author to attempt a description. He could not do this without extending the limits of this part of his work to too great a length : therefore, for information upon these subjects, the reader is referred to works on general medicine and surgery.

C A U S E S .

Concerning the causes of tumors of the palate, as well as those of other parts of the body, there exists some diversity of opinion. Some authors believe that they are attributable in all cases to a peculiar or specific constitutional vice, as venereal, scorbutic, cancerous, scrofulous, etc., while others think they may occur in individuals in whom no such habit or vice exists. That the character of the tumor is determined by the habit of body or constitutional tendency of the individual is a question, we believe, which, at present, admits of little doubt, though some exciting cause may be necessary to the commencement of the disease. Local irritation, no doubt, is the immediate or exciting cause of the various morbid productions of the palate, but this, unless favored by some specific or peculiar constitutional tendency or cachectic habit of body, would not be likely to give rise to their growth. Thus, while the former would seem to be the exciting cause, the character assumed by the disease, as has been just stated, is evidently determined by the latter.

Every habit of body, or tendency to any particular form of diseased action may be regarded, too, as having a susceptibility to morbid impressions peculiar to itself. Hence, an irritant which, in one case, might not be productive of any appreciable disturbance, might, in another, give rise to a morbid growth of a more or less malignant character—according to the habit of body, or constitutional tendency of the individual.

The irritation produced by dead, loose and diseased teeth, ulcers of the mucous membrane and necrosed bone, are, perhaps, among the most common of the exciting causes. Some may, perhaps, be disposed to question the agency of dental irritation in the production of a morbid growth from the palate, but the fact is too well established to admit of doubt. Many well authenticated cases are on record, which conclusively prove that diseased teeth are capable of exert-

ing a morbid influence upon these parts. M. GUYARD* reports the case of a woman, forty years of age, who had a cancerous excrescence of the palate, caused by the irritation produced by the superior incisors, and numerous examples of tumor and other diseases of the palate, resulting from the presence of diseased teeth, are given by Jourdain and other authors.†

But there are other causes, such, for example, as salivary calculus, mucous engorgement of the maxillary sinus, acrid saliva, and mechanical injuries from blows, and hard substances taken into the mouth. Roche and Sanson, in their *Theory and Practice of Medicine and Surgery*, say, that “from the irritation produced by syphilitic ulcers, carcinomatous tumors nearly always follow.”‡

TREATMENT.

Although tumors of the palate may sometimes disappear spontaneously on the removal of the exciting cause, the proper curative indication consists in their entire extirpation. When they are attached by a small base, this may be easily effected with a pair of scissors with properly curved blades, or by means of a ligature in the manner as directed for the removal of similar tumors of the gums. But when they are attached by a broad base, a curved bistoury is the most convenient instrument that can be employed, and sometimes it may be necessary to have two, a right and a left, or one for each side.

Boyer describes an operation which he performed for the removal of a hard, white, indolent tumor, of the size of a large nut, situated a little behind the middle of the palate, and which had occasioned the patient, who was a lady, no other inconvenience than an unpleasant sensation during

* Vide *Journal de Med.* tome. xix, p. 361.

† Vide *Traité des Maladies Chirurgicales de la Bouche.*

‡ Vide *Nouveaux Elements de Pathologie Medico-Chirurgicale, ou précis Théorique et Pratique de Médecine et Chirurgie*, tome 4, p. 1011.

mastication and deglutition. He excised the tumor with a bistoury, curved so as to fit exactly the vault of the palate, which he had made for the purpose. After having removed the tumor he destroyed the membrane from which it had originated, with a rasp. The hemorrhage was suppressed with vinegar and water and pledgets of lint. The wound soon healed, and at the expiration of eight years, there were no signs of a reproduction of the disease.*

In the removal of tumors from the palate, as well as from other parts of the body, no portion should be left; as, in this event, a reproduction of the disease would be likely to occur, and more especially if it be of a malignant character. The operation should be performed, too, before the tumor has acquired great size, or implicated in the diseased action, to a considerable extent, the neighboring structures.

There is always great danger when the morbid production is of a cancerous nature, however perfectly it may be removed, of its reproduction; to guard against this, as far as possible, the application of the actual cautery is recommended by many surgeons, not only for the purpose of causing exfoliation of a portion of the superjacent bone, but also to arrest the hemorrhage which generally attends operations of this sort. Boyer, who says he has performed the operation for the removal of tumors from the palate several times, frankly admits that he has never been successful where they were of a malignant character. But, notwithstanding the great liability there is of a reproduction of most morbid growths, this does not always happen, as is well attested by many cases on record, and from which it may be well to cite three or four.

Pierre Guyard reports in the *Journal de Médecine*, vol. xix, p. 361, and to which reference has before been made, the case of a woman, forty years of age, who had a cancerous excrescence of the palate, of many years standing,

* *Traité des Maladies Chirurgicale et des Operations, qui leur Conviennent*: tome 6, p. 449.

which weighed nine ounces. This excrescence was extirpated, and the patient restored to health.

The case of a man, forty years of age, affected with so large a tumor of the palate that he could take no nourishment, except in a fluid state, is reported by VARNER. In this case, it was of a cartilaginous character, interspersed with osseous points, and the operation for its removal was also successful.*

Jourdain describes the case of a man, who, from the irritation produced by the roots of several decayed teeth, had a swelling of the upper lip and nose, and a tumor of the palate of the size of a pigeon's egg. A fistula, traversing the alveolar and maxillary border, extended from the superior lateral incisor to the first molar of the same side, from which a large quantity of matter was discharged. The teeth being troublesome, were removed. The discharge of matter soon ceased. He next removed the tumor from the palate, which exposed a portion of necrosed bone; this exfoliated in a few days, leaving an opening into the nose of the size of a large quill, through which fluids, taken into the mouth, readily passed. By the application of caustics, the sides of the opening were caused to granulate, and in six weeks it had entirely healed.

The same author mentions the case of a lady, who had a tumor of the palate, caused by erysipelas. The last named disease having extended to the lips, nose and vault of the palate, caused in the last mentioned place ulceration, from the centre of which grew a small fungous tumor. This was removed, and a portion of the bone, which was exposed, was found to be in a necrosed and partially exfoliated condition. This was extracted with an excavator, and, under proper treatment, the patient soon recovered.

In presenting the foregoing cases, the author has not thought it necessary to give anything more than the important facts connected with each. A full translation of the

* Vide *Traité des Maladies Chirurgicales de la Bouche*, t. 1, p. 427.

reports would occupy more space than he wishes to devote to this particular subject.

It is seldom that the operation for the removal of tumors of the palate are followed by as favorable results as furnished by the foregoing cases. If it were necessary, many examples of tumors of the palate, attended with fatal effects, might be cited. Jourdain mentions one given by M. PLATER, of a cancerous tumor of the palate, caused by ulceration of the throat and uvula.

Both before and after the operation, such general or constitutional treatment as may be indicated by the habit of body or vice under which the patient may be laboring, should be adopted. If of a scorbutic or scrofulous habit, or affected with a syphilitic disease, suitable remedies should be prescribed, and when practicable, such local irritants as may have acted as exciting causes should be removed.

CARIES AND NECROSIS OF THE BONES OF THE PALATE, AND ULCERATION OF THE MUCOUS MEMBRANE.

The bones of the palate sometimes becomes the seat of caries and necrosis, causing ulceration of the subjacent soft parts, and the destruction of a greater or less portion of the structures which separate the cavities of the mouth and nose. Although these effects are of more frequent occurrence than tumors, they are less dangerous in their consequences. Commencing with inflammation and suppuration of the periosteal tissue, caries, and necrosis of the bones, accompanied by ulceration of the subjacent mucous membrane, soon supervene, and ultimately exfoliation takes place, when an opening of greater or less size, between the buccal and nasal cavities, is established.

During the progress of the disease, fetid sanies is continually discharged from one or more fistulous openings, into the mouth, and sometimes into the cavities of the nose, rendering the condition of the unhappy sufferer exceedingly

loathsome and distressing. The progress of the disease is often slow, continuing, not unfrequently, for weeks, months, and in some cases, even years, destroying all the pleasures of life, and rendering existence itself a burden. A case of this kind was recently introduced into the infirmary of the Baltimore College of Dental Surgery, which will be noticed at some length, when the author comes to treat of the means employed for remedying defects of the palatine organs.

Dr. B. B. Brown, surgeon dentist, formerly of St. Louis, Missouri, describes a very interesting case of the destruction of a large portion of the palate plates of the superior maxillary and palate bones, accompanied by the loss of the left lateral and central incisors.*

The ravages of caries and ulceration of the palate are sometimes so great that the palatine bones, the palate plates of the superior maxillary, the vomer, turbinated and nasal bones, together with the velum and uvula, are entirely destroyed, but when they are thus extensive, they are seldom arrested, except with the life of the patient.

The ulcerative process of the soft parts, when resulting from caries of the bones, frequently extends to the pituitary membrane, lining the floor of the nasal fossæ. A case of this kind, and to which the author will hereafter have occasion to refer, is related by Jourdain.

But ulceration of the mucous membrane, lining the vault of the palate, often occurs while the superjacent bones are in a healthy condition. It is frequently caused by inflammation and ulceration of the velum and uvula, whether resulting as an effect of secondary syphilis or from malignant ozena produced by other causes. But, from whatever cause the ulceration is produced, it may ultimately give rise to caries and necrosis of the bones.

* Vide Am. Jour. Dent. Sci. vol. 6, p. 236.

CAUSES.

As in the case of tumors of the palate, caries, necrosis, and ulceration of these parts are the result of local irritation and certain habits of body, or constitutional vices. The immediate or exciting cause is local irritation, but the extent of the effects resulting from such irritation is, as we have frequently stated before, in proportion to the susceptibility of the body to morbid impressions. The local irritants are the same as those which have been already mentioned, namely, dead and loose teeth, roots of teeth, salivary calculus, mechanical injuries, acrid humors, etc. The case of a lady of irreproachable character, is related by Jourdain, in whom a scratch on the palate with a fish-bone, caused a tumor, which suppurated and degenerated into an ulcer, with hard elevated edges and a fungus in the middle.* A case, in which effects similar to these, and produced by the same cause, was mentioned to the author in 1849, by a dentist of Baltimore. Local irritation, unquestionably, has much to do in the production of the diseases under consideration—more than many seem to imagine or are willing to admit. Most writers are of the opinion that they are wholly caused by some constitutional vice, and nearly always by the venereal, but that this opinion, to some extent at least, is erroneous, will be fully proven by some facts which will be presented when we come to speak of the treatment of these affections.

TREATMENT.

In the treatment of caries of the bones of the palate, it is important to ascertain if the patient be laboring under any constitutional vice which may have contributed to the disease, and the local irritants concerned in giving rise to it.

* Vide *Traité des Maladies Chirurgicales de la Bouche*, tom. 1, p. 407.

If the inflammation from which it results, is caused by mechanical irritation, the irritants should, at once, be removed. If decayed, dead, or loose teeth be suspected as having had any agency in its production, they should be immediately extracted, but so long as any portions of decayed or necrosed bone remains, it is needless to say, the ulcerations or fistulous openings in the soft parts cannot be healed. These, as soon as they have become sufficiently exfoliated, should be detached and removed, but in doing this it may be necessary to increase the size of the external opening. During the process of exfoliation, the mouth should be frequently gargled with astringent and detergent lotions, for the purpose of neutralizing the odor of the offensive matter which is continually discharging.

Suitable constitutional remedies should, at the same time, be prescribed. As in the case of tumors, if the patient be laboring under a scorbutic, serofulous or venereal diathesis of the general system, the indications should be properly fulfilled. But before instituting any general treatment, we should be well assured that our diagnosis is correct. A venereal vice is sometimes suspected when none exists, as is shown by the following brief summary of the history of a case related by Jourdain.

The subject of this case, was a man who had a swelling which occupied the whole of the left side of the vault of the palate, from which there had been a fistulous opening for a long time. The edges were hard and indurated. Venereal vice was suspected as the cause, and for which disease, treatment was proposed, but the patient not being willing to submit, Jourdain was consulted, who advised the removal of the roots of three or four teeth in the vicinity of the disease. This operation was performed and the fistulous opening at the same time enlarged, when the bone was found to be in a carious condition, but with little other treatment a complete cure was soon effected.*

* Vide *Traite des Maladies Chirurgicales de la Bouche*, tom. 1, p. 406.

That the effects resulting from dental irritation may extend to the palate, is shown by the following particulars of a case taken from the history of one given by the same author.

A man called upon Jourdain for advice, in relation to a tumor of the vault of his palate. Upon examination, a sensible fluctuation was perceived; on being pressed, fetid pus escaped from a small fistulous opening between the right lateral incisor and canine tooth, and also from the socket of the second bicuspid, which had been extracted a short time before. The opening from the alveolus of this tooth communicated with the first mentioned fistule and the disease in the palate. Notwithstanding these two outlets for the escape of the matter, it increased in the palate. Various means were resorted to for the cure of the disease, but without success. The nasal fossæ, by the accumulation of matter, were partially closed, the alveoli of the lateral incisor, cuspidatus and first bicuspid became necrosed, the teeth loosened, and were extracted. The alveoli exfoliated, the tumor of the palate was opened, when the bones of the palate and maxillary alveolar borders were found in a necrosed and partially exfoliated state. These were removed without much difficulty, and left an opening through to the pituitary membrane which lined the floor of the nasal fossæ. These portions of bone having been removed, the parts soon healed.*

That the caries in the two last cases was caused by dental irritation, there can be no question, and that it often results from this cause, we have not the least doubt. In the last case, it is probable that the second bicuspid of the affected side, was not extracted until an abscess had formed at the extremity of its root, and that the matter, instead of escaping externally, had effected a passage through the inner wall of the alveolus and thence between the palate plate of the superior maxillary and mucous membrane to near

* Vide *Traite des Maladies Chirurgicale de la Bouche*, tome. I, p. 397.

the median line, where it had accumulated, produced the tumor mentioned by Jourdain, and ultimately made a passage for its escape between the lateral incisor and cuspidatus. Several cases, followed by very similar effects, have fallen under the immediate observation of the author.

But when favored by a cachectic habit of body or venereal vice, the effects are more destructive, and in this case, local treatment will not suffice.

Ulceration of the palatine mucous membrane may occur without caries of the subjacent bone; it may result as a consequence of ulceration or other disease of the velum or uvula, or from some mechanical injury inflicted upon the parts. When it is of a simple nature, cooling and astringent gargles, preceded by mild aperients, will generally suffice for its cure. If dependent upon a specific constitutional tendency or vice, appropriate general remedies should be employed. But with regard to the treatment of ulcers of the palate, we shall have occasion to speak when we come to treat of the diseases of the velum and uvula.

INFLAMMATION AND ULCERATION OF THE VELUM AND UVULA.

The velum palati and uvula sometimes become the seat of inflammation, accompanied by pain, increased redness, difficult deglutition and articulation of speech. Most frequently it terminates in resolution, but sometimes in ulceration, and at other times in gangrene. When resolution is the termination, it gradually subsides, after having continued for a greater or less length of time. When by ulceration, one or more white or ash colored spots appear upon the velum and uvula, after it has continued for a certain period, and when, by gangrene, the part, after having assumed a dark purple or almost black color, sloughs. This latter termination, fortunately, rarely happens.

As a consequence of inflammation, the uvula sometimes becomes tumefied and elongated; at other times it becomes elongated when there is no apparent tumefaction.

In the latter case, it is vulgarly termed a "falling of the palate." Most frequently when it is elongated, its thickness is at the same time increased. In this case there is an increase of redness, but when there is elongation, without an increase of size, resulting simply from relaxation of the part, its color, instead of being heightened, is often diminished, presenting a whitish or semi-transparent appearance. This description of elongation is termed serous tumefaction of the uvula. It is seldom accompanied by pain.

When the uvula becomes so much elongated as to rest upon the tongue, it causes irritation, difficult deglutition, oftentimes a sense of suffocation, the frequent expulsion of mucus from the throat, and sometimes a disagreeable cough.

Ulcers of various kinds sometimes attack these parts, though they are less subject to them than are the other parts of the mouth, fauces and tonsils. Sometimes the ulcers are of a simple nature, at other times they are aphthous, scrofulous, scorbutic, venereal or cancerous, according to the specific poison or diathesis which has given rise to them. When the ulcer is not dependent upon constitutional causes, it is termed a simple ulcer, and is nothing more than a granulating sore which secretes healthy purulent matter.

Aphthous ulcers at first appear in the form of whitish or transparent vesicles, which break, and are ultimately transformed into ulcers, either surrounded by a slightly elevated edge of a reddish color, or spread and unite with each other. The former are termed *discrete*, and the latter *confluent*, aphthæ. But ulcers of this kind generally appear in other parts of the mouth and fauces before they attack the velum and uvula of the palate.

The velum and uvula are, perhaps, more subject to venereal, than to any other kind of ulcers. The characteristics of these are, sometimes, very similar to ulcers which result from some other specific constitutional vice, and their character can only be positively determined by ascertaining all

the other circumstances connected with the history of the case. They are generally preceded by ulceration of the throat, dull heavy pain, especially at night, increased redness of the parts, swelling of the uvula, and difficult deglutition. They usually have a whitish, dirty gray, or ash colored appearance, with slightly elevated and irregular margins, and secrete thin ichorous matter of a very fetid odor. The surrounding parts are preternaturally red, and sometimes present an almost purple appearance. At other times the ulcers appear in the form of aphthous specks, followed by sloughing of the surrounding parts. Sometimes the ulcers attack the posterior side of the velum and uvula first, where they commit extensive ravages before they appear anteriorly. From these parts they often extend to the vault of the palate, but more frequently, when they appear here, the periosteal tissue and bones are diseased before ulceration shows itself in the mucous membrane.

Ulcers of the velum and uvula sometimes arise as a consequence of protracted and immoderate use of mercury. When they result from this cause, they are preceded by a copperish taste in the mouth; increased flow and viscosity of the saliva; tumefaction and increased sensibility of the gums, looseness of the teeth; a peculiarly disagreeable odor of the breath, general debility and emaciation, and sometimes diarrhea. The gums, edges of the tongue, mucous membrane about the angles of the jaws, inner surface of the cheeks and throat, ulcerate before the velum and uvula are attacked.

The velum and uvula are sometimes the seat of other bad conditioned ulcers, such as the cancerous, scrofulous, etc.

C A U S E S .

Inflammation of the velum and uvula most frequently result from irregular exposure to cold and moisture, though it may sometimes be produced by local irritation, as mechanical injury, acidity of the gastric and buccal fluids.

Ulceration of the parts may result from the same causes, but the character which the ulcer assumes is determined by the habit of body, or peculiar diathesis of the general system. Elongation of the uvula is caused either by inflammation and general enlargement, relaxation of the parts, or serous infiltration of its apex.

T R E A T M E N T .

For simple inflammation of the velum and uvula, unaccompanied by fever or other general constitutional effects, little else will be required than gargling the throat with an infusion of capsicum, sweetened with honey. When the inflammation is severe, and the vessels have the appearance of being distended, advantage may be derived from scarifying the parts.

But when the uvula is so much elongated as to rest upon the tongue, and cause a sensation of suffocation or a troublesome cough, if it does not yield to exciting and astringent gargles, it may become advisable to remove a portion of it.

FIG. 247.

For this operation, though an exceedingly simple one, a variety of instruments have been invented. The best however, which the author has seen, is the one invented a few years ago by the late Dr. S. P. Hullihen, of Wheeling, Va. This instrument, although very simple in its construction, is an exceedingly useful one, for, at the same time it cuts

the uvula, it secures the excised extremity, and prevents it from falling.

The construction of this instrument, and the manner of using it are so very simple, that the accompanying engraving will supersede the necessity of any description.*

For a simple ulcer of the velum or uvula, no other treatment will be required than to gargle the throat occasionally with some gently stimulating and astringent lotion; the one recommended for inflammation of these parts, may generally be employed with advantage.

In the treatment of venereal or syphilitic ulcers of the velum and uvula, little advantage will be obtained from local remedies. They can only be cured by appropriate constitutional treatment, such as is prescribed in works on general medicine and surgery. To these, therefore, the reader is referred for information upon this subject.

In cases of mercurial ulcers, it is desirable that two or three liquid evacuations from the bowels should be procured daily. For this purpose, sulphate of magnesia or sublimed sulphur may be administered night and morning. The mouth should, at the same time, be gargled six or eight times a day with some gently astringent lotion. A weak solution of the sulphate of zinc, or alumina, sweetened with honey, may sometimes be advantageously employed, but more benefit, perhaps, will be derived from the use of a solution of the chloride of lime. When the pain is so severe as to prevent rest, opium should be prescribed. The diet of the patient, for the most part, should consist of farinaceous substances, and after the ulcers have begun to heal, milk, light soups, etc., may be recommended.

In the treatment of scirrhus and other ill-conditioned ulcers of the velum and uvula, dependent upon a cachectic habit of body, it is necessary that the constitutional indications should be properly fulfilled, and that the vitiated action of the disease should be changed by the application

*An engraving and description of Dr. Hüllihen's uvula scissors is contained in vol. 7, No. 3, of Am. Jour. and Lib. of Dental Science,

of local irritants, such as caustics. The application of the actual cautery has been found more efficient in changing the condition of ulcers of this sort, and exciting a healthy action in them, than any other means which have been employed.

For cancerous ulcers, it has been found necessary to remove a greater or less portion of the velum and uvula, and even this operation has seldom proved successful; for the disease, after a greater or less length of time, reappears in some of the neighboring parts.

CHAPTER SECOND.

DEFECTS OF THE PALATINE ORGANS.

THE nature and extent of the defects of the palatine organs are various. They sometimes consist of a simple perforation of the vault of the palate ; this may be either in the centre, or on either side of the median line. At other times, the loss of substance extends to the entire vault and velum. Nor is the loss always confined to these parts ; it sometimes extends to the anterior part of the alveolar border, and a portion of the upper lip, constituting what is usually termed hare-lip.

The defects of the palatine organs, as we have before stated, may be divided into accidental and congenital. The first, we have said, results from accidental causes—the second from malformation of the parts.

ACCIDENTAL DEFECTS.

Accidental lesions of the palatine organs are divided by M. Delabarre into three species. The first consists in perforations of the vault of the palate ; the second, in perforations of the velum, and the third, in the destruction of the entire vault of the palate, or of a great portion of it. To this last might also be added the destruction of the whole, or a large portion of the velum, as well as of the vomer, part of the alveolar border and turbinated bones.*

* Vide *Traité de la Partie Mécanique de l'Art du Chirurgien Dentiste*, t. 1, p. 294.

It has also been remarked, that lesions of the palate and velum, resulting from disease, differ from congenital defects. The first most frequently perforate the side of the palatine vault, and communicate with only one nostril, whereas, the latter, as will presently be seen, occupies the centre of the arch, and penetrates both of the nasal cavities.

The causes of accidental lesions or defects of the palate and velum, have already been treated of, and the manner of remedying them will hereafter be described.

CONGENITAL DEFECTS.

Congenital defects of the palate occupy the median line or palatine raphæ, and consist in a division of the osseous and soft textures, of greater or less extent. This division is sometimes confined to the vault of the palate; at other times the velum, anterior part of the alveolar arch and upper lip participate. It forms a communication with both nostrils, and when the malformation extends to the alveolar border, and upper lip, which is divided vertically in one, and sometimes in two places, it gives to the mouth a most disagreeable aspect. But hare-lip is sometimes met with when there is no imperfection of the osseous structures, and imperfections are often met with here when the lip is perfect. In some cases the cleft or fissure is more than three-fourths of an inch wide throughout the whole extent of the palate and velum, accompanied by absence of the whole of that portion of the alveolar border which should be occupied by the four incisors; at other times the alveolar arch is divided in two places, leaving a portion between the lateral and central incisors, or one lateral and one central, after projecting more or less, and thus very greatly increasing the deformity. Although a double hare-lip, with two divisions of the alveolar border, is seldom met with without some defect of the palatine organs, cases do occasionally occur. Dr. Sims, a skillful and ingenious surgeon, formerly of Montgomery, Ala., describes a most interesting case of this kind,

in vol. 5th, page 51, of the American Journal of Dental Science.

Congenital defects of the palate are sometimes accompanied by more or less deformity of the sides of the alveolar arch, and of the teeth. Sometimes the sides of the alveolar ridge are forced too far apart, and at other times they are too near each other, while the teeth are either too large or too small, with imperfectly developed roots, and generally of a soft texture.

Want of coaptation, resulting from defect of formation in the palatine plates of the maxillary and palatine bones, are the cause of congenital deficiencies of the parts in question. But that such malformation should occur here while all the other parts of the body are well developed, is wholly inexplicable, though not more strange than that other organs, as the hands, feet, &c., should be deformed, while these parts are perfect. What it is that interferes with the laws that govern the development and growth of the organs of the body during intra-uterine existence, is a mystery which physiology has not yet been able fully to unravel.

Thus it is seen, that the defects of the palatine organs which result from malformation, present as much diversity of character as do those which are produced by disease, or other accidental causes. Mr. Stearns, of London, in a very able and highly interesting paper, published in the London Lancet, on "Congenital Fissure of the Palate," in noticing their various anatomical peculiarities divides them into three classes.

The first class embraces all the cases in which the fissure extends through the velum, palate, and maxillary bones, to the alveolar border, and, sometimes, "through the whole extent of the median symphysis." This form of fissure is the most extensive, and justly regarded as the worst, and "is usually complicated with hare-lip."

In the second class the bones of the palate are "apparently entire, though the concavity of the arch may be somewhat greater than usual, and the fissure" extend a

short distance into their "posterior margin." The lesion, in this case, is almost wholly confined to the velum palati.

The third class embraces those cases in which the fissure is confined to the soft parts, extending, perhaps, only a short distance up into the uvula. This form of fissure is, probably, less frequently met with than either of the preceding.

FUNCTIONAL DISTURBANCES, RESULTING FROM DEFECTS OF THE PALATINE ORGANS.

The principal effects resulting from an absence of a portion of the palatine organs, are, as we have before stated, an impairment of the functions of mastication, deglutition and speech. Distinct utterance is sometimes wholly destroyed, and mastication and deglutition are often so much embarrassed as to be performed only with great difficulty. These effects are always in proportion to the extent of the separation or deficiency of the parts. But in noticing the effects which result from absence of a portion of the palatine organs, we shall first speak of those which are produced upon the functions of mastication and deglutition.

Although the simple act of triturating the food, may not be materially impaired by the absence of a portion, however extensive, of the palatine organs, unless the natural relations of the teeth of the upper and lower jaws are changed, still the process is more or less interfered with, as substances taken into the mouth cannot be so readily managed, as when the parts are in their natural state. They are constantly escaping from the control of the tongue, and passing up into the cavity of the nose.

In cases of congenital defects of the palate and velum, it is difficult to conceive how, in infancy, the child manages to obtain from the breast of its mother or nurse, the food necessary for its subsistence; yet, even where the anterior part of the alveolar border, and a part of the upper lip are

wanting, it does, in accordance with the suggestions of natural instinct, by means of a peculiar mechanical process, contrive to do it. The expedient to which it resorts for effecting this process is curious. The nipple, instead of being seized between the tongue, upper lip and gum of the alveolar border, is taken between its lower surface, and the under lip and gum of the inferior alveolar ridge, and in this way it manages to extract the nourishment necessary for its subsistence and growth. The tongue, as is remarked by M. Delabarre, is thus made to close the opening in the palate, and perform the office of an obturator. By contracting the lip and depressing the tongue, the milk is drawn from the breast of the mother or nurse. At this young and tender age, the child is not conscious of the imperfection of its palate, and it is not, until the period arrives when it should begin to make its wants known by words, as is remarked by the author just mentioned, that it feels the importance of the functions of speech and begins to realize the misfortune with which it is afflicted.

But as the child arrives at this period, the mechanism of sucking, as M. Delabarre observes, is perfected, and ultimately applied to the mastication of solid aliments. "When chewed, it is conveyed between the tongue and movable floor, which serves for a point d'appui to it, and thence it is brought back between the teeth. Thus it is, that the complicated operation of mastication and deglutition is performed without the alimentary morsel getting into the nose; or, if this does sometimes happen, it is the result of accident." But in cases of accidental lesion of the palate, the individual has not the advantage, as the author just quoted observes, "of early infancy." Those who are afflicted with accidental lesions, no matter what may be their position and extent, "having," as the author says, "acquired the habit of eating, by placing the aliment on the tongue, can take no nourishment, without a part of it getting into the nose." When to this inconvenience is added a change in the natural relations of the teeth of the two jaws, mastication is

rendered still more difficult and embarrassing. When this is the case, the tubercles of the teeth of one jaw, instead of being received into the depressions of those of the other, strike upon their protuberances, and cannot be made to triturate the food in as thorough and perfect a manner as is required for healthy and easy digestion. Thus, not only is the process of mastication rendered imperfect, but it is also more tedious.

The process of deglutition itself, so long as the velum and uvula are perfect, is not materially affected by a perforation simply of the vault of the palate, although much difficulty may be experienced in conveying alimentary and fluid substances to the fauces and pharynx. But when this curtain is cleft or partially or wholly wanting, it is rendered very difficult, for, by the contraction of the muscles of the pharynx, part of them are forced up into the nose. The reason of this will appear obvious, when we take into consideration the form and functions of this movable appendage. When its muscles are relaxed, it forms a slightly concave curtain; but in the act of deglutition, the muscles contract, raise the velum and close the opening from the pharynx into the posterior nares. Thus alimentary substances and fluids are prevented from escaping into the nose.

It matters not, therefore, whether the imperfection of the velum palati be the result of accident or disease, its effects upon deglutition are the same. In proportion as the lesion or deficiency is great, will this operation be rendered difficult and embarrassing. M. Delabarre mentions the case of an individual, who, in consequence of an imperfection of the palate, could swallow no fluids without a part being returned by the nose. To obviate this inconvenience, he had to throw his head sufficiently far back to precipitate them into the esophagus. This is an expedient to which others, thus affected, have been compelled to resort.

Imperfection of speech always results from an opening in the palate, for this gives to the voice a nasal twang, and

renders the formation of some sounds impossible. The loss of the teeth, though never to the same extent, is productive of the same effect. But to fully comprehend the manner in which a lesion of the palate may affect the utterance of speech, it will be necessary to understand the agency which the several parts of the mouth have in the formation of articulate sounds.

Speech consists in the combination of sounds produced by the organs between the glottis and external opening of the mouth. The co-operation of the several parts of the mouth are necessary for the formation of most sounds,* and hence, if any of these be defective or wanting, the power of forming such sounds is either partially or wholly destroyed.

* Müller's Physiology, vol. 2, p. 1045.

CHAPTER THIRD .

MANNER OF REMEDYING DEFECTS OF THE PALATINE ORGANS.

DEFECTS of the palatine organs are sometimes remedied by means of a surgical operation, termed *staphyloraphy* ; but more frequently, by supplying the deficiency of the natural parts with a mechanical substitute. The operation of staphyloraphy, when it can be successfully performed, is the best and most perfect method that can be adopted for remedying imperfections of the parts in question. The application of a mechanical substitute, though it may not completely restore the functions dependent upon the integrity of the natural parts, will often so improve them, as to render the inconveniences resulting from their imperfection, scarcely perceptible.

In treating upon the above methods, we shall first describe the operation of staphyloraphy, and, afterwards, the various mechanical appliances employed for the purpose, which are designated by the names of *obturators* and *artificial palates*.

STAPHYLORAPHY.

It rarely happens, except in cases of congenital fissure, that the operation of staphyloraphy can be successfully performed, and only then, when the edges of the cleft velum are firm and can be easily brought together. There are many ways by which the success of the operation, even in apparently the most favorable cases may be defeated. For

example, the ligatures may be detached by attempting to swallow, or clear the throat, or by coughing, sneezing, or by inflammation and sloughing of the parts. Unless these are carefully guarded against, the best efforts of the surgeon may be frustrated.

The idea of this operation was first conceived by an ingenious French dentist, by the name of LE MONNIER, who attempted, and with success, to perform it as early as the year 1764. But for more than half a century afterwards, it does not seem to have attracted any attention, or to have been generally known to the medical profession. In 1819, however, M. Roux, a celebrated French surgeon, and author of an able memoir upon the subject, published in 1825, performed the operation upon Dr. Stephens, a young American physician.* In 1820, it was performed for the first time in the United States, by Dr. J. C. WARREN, of Boston, and in 1822 in England, by MR. ALCOCK.† Now, it is classed among the regular operations of surgery.

As the success of the operation depends in a great degree upon the consent of the patient, he should, as a general rule, have attained a sufficient age to enable him to appreciate its importance, before it is performed. Dr. HULLIHEN, however, a scientific dentist of Wheeling, Va., says, he has performed the operation with success on a child of nine years of age, but the author is of the opinion, that it is generally better to defer it until after the fifteenth or sixteenth year; and the natural excitability of the parts should be, previously, as much lessened as possible, by frequently touching and moving them about with the finger. This should be done several times a day, for at least two weeks before the ope-

* We are informed by Velpeau, in his *Elements of Operative Surgery*, p. 428, that M. Colombe performed the operation on a dead subject in 1813, and in 1815 endeavored to prevail on a patient to permit him to repeat it, but without success. In 1817, too, M. Graefe published in *Hufeland's Journal* some details concerning it, but the subject elicited no interest until M. Roux performed the operation in 1819.

† Vide Dr. Reese's Appendix to Cooper's *Surgical Dictionary*.

ration is attempted, and during this time, the patient should be restricted to a spare diet.

The operation of staphyloraphy, or velosynthesis, consists in removing the margins of the divided velum with a pair of curved scissors, as recommended by M. Roux, or a double-edged knife, and holding the raw edges in contact with each other until a union takes place.

A number of ingeniously contrived instruments have been invented for the performance of the operation, but all that are really necessary, are, a sharp hook, a double-edged knife, short curved needles, a needle-holder, (*porte-aiguille*,) strong waxed ligatures, a pair of long-handled curved forceps, and scissors; other instruments may, in some cases, be required. In addition to the above, water, towels, and one or more assistants, will be needed.

Thus prepared, the patient, after having been previously submitted to the necessary preparatory treatment, should be placed in a chair facing a good light, with his head firmly supported by an assistant, and his mouth open; the operation may be commenced by inserting the hook into the margin of the velum, near its most dependent part, on the left side of the fissure, in the manner as represented in Fig. 248. This instrument, held by an assistant, should be depressed so as to make the margin slightly tense. The point of the double-edged knife may now be placed below the most dependent part of the velum, a little to the left of where the hook is inserted, (see Fig. 248,) and carried from below upwards until it has reached the angle of the

FIG. 248.

fissure, removing about one line of the margin. This operation may be repeated on the opposite side of the fissure, or

FIG. 249.

FIG. 250.

by changing the knife from the right to the left hand, and directing the assistant holding the hook to pass his hand "across and a little above the face of the patient," in the manner as described by Dr. Mütter, so as to keep up a constant traction upon the strip of mucous membrane removed by the first cut, the right margin of the fissure may be made tense, and the knife carried from above downwards, completing, by a single incision, the whole of this part of the operation.

Further procedure should be suspended until the hemorrhage, though seldom very great, shall have partially subsided. A needle, armed with a well waxed ligature, and held in a pair of suitable forceps, should be passed

from before backwards through the most dependent part of the left margin, about three lines from the edge. As soon as it is seen on the opposite side, it should be grasped by the assistant with a pair of longhandled forceps, and as soon as the hold of the porte-aiguille is relaxed, drawn through, replaced in the latter, and passed through, from behind for-

wards, the right margin of the velum opposite to the ligature in the left. See Figs. 249, 250. After the patient has rested a few minutes, a second, third, and, when necessary, a fourth ligature should be introduced.

The passage of the needle through the left margin of the velum is represented in Fig. 249, and in Fig. 250, through the right margin from behind forwards.

The ligature first introduced should now be tied, bringing the edges of the velum close together, and, afterwards, the second and third, cutting off the ends of each. After the first knot of the ligature is tied, some precaution should be used to prevent this from slipping, while the second is tied. The method adopted by M. Roux for knotting the ligature is, to make the first fold of the knot with the fore-finger of each hand placed back to back, and after this has been drawn sufficiently tight, it is seized by an assistant with a pair of forceps, and held until the second and last turn of the knot is made.

FIG. 251

FIG. 252

Some surgeons use two needles for each ligature—one at each end, and introduce them from behind forwards—one

through each margin of the divided velum, instead of one, as in the method just described.

The following cut, Fig. 253, copied from Liston's and Mütter's Surgery, represents the needle-holder, or "porte," of Schwerdt, which is, perhaps, as well adapted to the purpose as any instrument that can be employed. Dr. Physic's forceps have also been used, but Dr. Mütter thinks this a preferable instrument.

FIG. 253.

After the operation has been performed, the patient should be directed to keep his mouth closed, maintain perfect quiet; avoid coughing, sneezing, or even spitting, and the use of all solid food. Nor should he take but very little aliment, and this only at long intervals. For appeasing the cravings of the hunger with which some suffer, Dr. Mütter recommends "thin calf's-foot jelly, or what is known as cold custard slip," as the best nourishment that can be used, but he thinks neither should be given until after the second or third day after the operation has been performed.

In the performance of the operation of staphyloraphy, however, different surgeons employ different instruments, and adopt different methods of procedure. Professor N. R. Smith, of Baltimore, who has performed the operation five times, and in three cases with perfect success, employs a very simple needle, of a lance shape, mounted on a handle, and having a slit near its point which opens at its posterior end. The needle is broader in front of this eye than behind it, which renders the passage of the back part more easy. Armed with a ligature, the curved portion of the needle is carried beyond the fissure, and its point introduced "behind the middle of the uvula," and as soon as it has come through far enough to expose the ligature in the slit, it "is taken

hold of with a tenaculum, disengaged from the slit or eye in the needle," when "the latter instrument is withdrawn." A second ligature, in like manner, is introduced "half an inch higher up," and a third, if necessary, "at an equal distance from the second. With the ends of the ligature passed through the uvula, this part is drawn forwards," until the fissure in the soft plate shall assume nearly a "horizontal position," its edges are then cut off with a "pair of scissors, either straight or curved laterally," or with a bistoury and a pair of forceps. This done, the ligatures are tied, and the ends cut off.*

Dr. J. C. Warren, of Boston, who has performed the operation a number of times, uses a needle of his own invention, with a movable point. Dr. J. M. Warren, son of Dr. J. C., has also performed the operation a number of times, and with very great success. When it extends up into the hard palate, he dissects the mucous membrane from the bones on each side of the fissure, carrying his knife sufficiently forward towards the alveolar border, to form a flap broad enough to meet a like one from the opposite, along the median line.

Dr. Hullihen, who has performed the operation several times, has invented a very ingenious needle-holder, which, we have no doubt, will ultimately supersede the use of most others.†

When the fissure is so wide as to prevent the margins of the velum from being brought together, Dr. METTAUER, of Virginia, recommends making several lateral incisions through the mucous membrane, with a view to increase the extent of the velum, and thus permit their edges to be brought together. Mr. FERGUSON proposes, for the more easy and perfect accomplishment of this end, the division of the levator-palati, the palato-pharyngeus, and the palato-

* Vide Appendix to Cooper's Surgical Dictionary, by Dr. Reese, p. 126.

† A description of this instrument, together with Dr. Hullihen's method of performing the operation, is given in vol. 5th, of the American Journal of Dental Science.

glossus muscles. The motory influence of the muscles, in an upward, outward and downward direction, being thus, for a time, cut-off, he believes the motory power of the soft palate will be so much destroyed, that the edges of the fissure may be brought together.*

FIG. 254.

For supplying deficiency of structure, DIEFFENBACH recommends a longitudinal incision a short distance from the margin of the fissure, in the manner as seen in Fig. 254, copied from Dr. Pancoast's Operative Surgery. The last named gentleman has performed the operation in two cases, with success. Dr. Mütter, of Philadelphia, who has been very successful in the operation, has also had

recourse to these lateral longitudinal incisions, with the most happy results.†

When the inflammation which follows the operation is very severe, it should be combated by general and local bleeding, and such other antiphlogistic means as the nature of the case may seem to demand. When the inflammation is accompanied by cough, Dr. Mütter recommends the administration of opiates. The same author recommends, in case sloughing of the parts takes place, the application, with a camel's-hair pencil, of a solution of the nitrate of silver, or a mixture of creosote and water, "three or four times a day."

It often happens, that an opening remains in the palate after the velum has been successfully united. This may sometimes be closed by the granulation of the edges of the

* Vide Medico-Chirurgical Transactions, vol. 28.

† Vide Liston's and Mütter's Surgery, p. 204.

cleft, which may be induced by making them raw by the application of caustic or the actual cautery. Dieffenbach has employed, with success, a concentrated tincture of cantharides, applied several times a day to the edges of the opening.* By some, the actual cautery is preferred, but if the latter be used, it should only be heated sufficiently to blister the parts.† The nitrate of silver and potassa pura have been used, but there is danger of causing a greater loss of substance by the use of these powerful caustics than can be gained by the granulations which they induce.

A surgical operation is seldom performed for the purpose of closing a simple opening in the hard palate. It has been recommended, however, by some surgeons, and when the hole is not very large, the operation of *staphyloplasty* may be successfully performed. In Fig. 255, copied from Dr. Pancoast's Operative Surgery, the operation as performed by the author of this valuable work, is represented, and so perfectly

FIG. 255.

is it exhibited in the cut, that we do not deem any further description necessary. In the majority of cases of this kind, however, an artificial obturator or palate will be found necessary.

* Vide British and Foreign Medical Review, for April, 1846.

† Vide Dr. Hullihen on Cleft Palate, in Am. Jour. Dent. Science, vol 5, p. 173.

ARTIFICIAL OBTURATORS AND PALATES.*

Although by the operation of staphyloraphy, the use of mechanical contrivances for remedying imperfections of the palate, are often rendered unnecessary, yet, in the majority of cases, it is only by such means that any relief can be afforded. Artificial palates and obturators have been employed for a long time.

They were, according to GUILLEMEAN, applied by the Greek physicians, but it is to that celebrated French surgeon, Ambrose Paré, that we are indebted for the first description of an appliance of this sort. This author has furnished an engraving of an obturator which he had constructed in 1585, consisting of a metallic plate, probably of silver or gold, fitted to an opening in the vault of the palate. It was held up by means of a piece of sponge, fastened to a screw in an upright attached to the upper surface of the plate.

The employment of sponge, however, was found to be objectionable, as the secretions of the nasal cavities which it absorbed, soon became insufferably offensive, but notwithstanding, it continued to be used for a long time. Ultimately, however, it was superseded by an obturator invented by Fauchard. This was held up by means of wings, which turned on a pivot. Both of these obturators, however, exerted a hurtful influence upon the surrounding parts, as the pressure produced by the sponge and wings caused them to be gradually destroyed, and thus augmented the evil they were designed to remedy, consequently, their use has been wholly

* Although a distinction is made by some writers, between the terms artificial palate and palatine obturator, there does not seem to be much propriety in it, since they both signify one and the same thing, namely, an instrument to *close or stop* an opening in the palate. The former term, however, is generally applied to a simple plate fitted to the palatine arch, the latter, to a plate surmounted by a piece of sponge, wings, or a drum or air chamber, passing up into or through the opening, and designed either to hold up the plate, or to fill the aperture. When a velum is attached, the instrument is termed an artificial palate with a velum.

abandoned. We do not, therefore, deem it necessary to give a description of either. We will, however, quote a passage from Bourdet upon the subject. In alluding to the impropriety of having recourse to any appliance which has a tendency to counteract the curative efforts of nature, he says, "Before considering the cicatrised perforations of the palate as being of a nature incapable of diminishing in diameter, practitioners should satisfy themselves properly and beyond doubt, that such is the case. We do not think so, for positive facts attest the contrary, and as holes made in the cranium with the trepan closed almost entirely, in like manner, those of the palate constantly diminish." Numerous examples might be adduced if it were necessary to prove the impropriety of sustaining an obturator by any fixtures which act upon the lateral parts, as they necessarily tend to increase the dimensions of the opening in the palate. Cases do, however, sometimes occur, in which no other means of support are offered, and then the dentist may, perhaps, be justifiable in using them.

With a view of obviating the objections which have been mentioned as existing to the obturators of Paré and Fauchard, Bourdet proposed to employ simply a metallic plate, fitted to the vault of the palate and large enough to cover the opening, with two lateral prolongations, one on each side, extending to the teeth, to which they were fastened by means of ligatures. This was also found to be objectionable, as the ligatures were productive of constant irritation to the gums, and besides they did not hold the plate with sufficient stability in its place. Its use was, therefore, soon abandoned. But these objections were both obviated, as we have stated in another place, by an improvement made by M. Delabarre, which consists in the employment of clasps, instead of ligatures attached to lateral branches of the plate, and to prevent these from slipping too high up upon the teeth, he attached to each a kind of spur, which was so bent as to come down over the grinding surface of the one to which it was applied. The last named author, also, made

another equally valuable improvement, which consisted in the application of a drum to the upper surface of the plate. The object of this was to prevent the accumulation of mucous fluids from the nose, in the *cul-de-sac*, formed by simply closing the opening below, and to prevent fluids, in swallowing, from passing up between the obturator and soft parts, through the opening into the nose.

The manner of constructing an obturator, with a drum upon its upper surface, is as follows: First take an impression of the entire palatine vault and alveolar ridge in wax. From this, a plaster and metallic model and a counter-model are procured, in the manner as before described; a gold plate is then swaged between the two last, a little larger than the opening in the palate, with a broad arm on each side, extending to a bicuspid or molar tooth, to which a broad clasp is fitted. This is soldered to the arm from the plate. Second, an impression of the opening in the vault of the palate with wax, properly softened and placed upon the upper surface of the palate plate, is now taken, using the precaution to prevent forcing it up too far through the aperture; this is next trimmed where it comes in contact with the plate, so that it shall not be quite as large as the opening: it is then covered with plaster, after which a metallic model and counter-model is taken, then a gold plate is swaged between the two, and this last is fitted and soldered to the palatine plate. The piece after being properly finished, is now ready to be applied.

It is of the greatest importance that an artificial palate or obturator should be executed in the most perfect manner, and be made to fit accurately to all the parts with which it is to be in contact, so that it may not produce the slightest irritation or exert undue pressure upon any of the superjacent or surrounding parts. As in the case of the application of a dental substitute, the piece should not be applied while any of the teeth, especially those of the upper jaw, are in an unhealthy condition. The gums and sockets of the teeth should also be free from disease. The piece, too,

should be removed two or three times every day, and thoroughly cleansed, as also the teeth to which the clasps are applied.

A SIMPLE PALATE PLATE, OR PALATINE OBTURATOR.

When the opening in the palate is small and has no connection with the velum, it is seldom necessary to raise the upper surface of the plate by attaching a drum or air-chamber to it. If it be accurately fitted to the vault of the palate, it will effectually prevent fluids in deglutition

from passing up into the nasal cavities, or the escape of any portion of the voice through the opening, and by frequently removing the plate, it will prevent the stagnation of the secretions which may accumulate in the *cul-de-sac*. A simple plate like the one represented in Fig. 256, will be all that is required to remedy the defect.

Although the stability of the plate will very much depend upon the width of the clasps, the latter should never be so wide as to press upon the gums around the necks of the teeth to which they are applied, as in that case they will be productive of irritation, and ultimately cause the destruction of the alveoli and loss of the teeth. Nor should they press upon the teeth so as to force them apart or draw them towards each other, as, in either case, the effect would be, gradually to loosen and displace the organs. In short, the same precautions are necessary in the application of clasps to a palate plate, as to one which is to serve as a support for artificial teeth.

FIG. 256.

A PALATE PLATE, OR OBTURATOR, WITH A DRUM UPON ITS UPPER OR CONVEX SURFACE.

FIG. 257.

An obturator of this description is seldom required, except in those cases where the opening in the palate is connected with the velum, so that by the contraction of its muscles, the parts are raised from the plate in such a manner as to permit fluids, in the act of deglu-

tition, to pass up into the nose. In this case it will not only prevent this difficulty, but it will also prevent the fluids of the nose from accumulating in the opening above the plate.

As the manner of constructing an obturator of this description, (see Fig. 257,) has been already described, it will only be necessary to add, that in fitting and adjusting the drum to the upper surface of the plate, great care is necessary to prevent placing it to one side of the opening. After it has been properly adjusted and one side of it soldered to the palate plate, a hole should be drilled through it for the escape of the heated air, while the remainder of the soldering is effected. This done, the whole may be closed by the introduction of a screw of the same metal, which may afterwards be filed off even with the surface of the plate.

In the construction of an obturator, like either of the foregoing, but little ingenuity or artistical skill is required, as the mechanism is of the simplest description. The adaptation, however, should be perfect, and the execution neat. The gold should also be sufficiently fine to prevent being acted upon by the secretions of the buccal or nasal cavities.

AN ARTIFICIAL PALATE, WITH A VELUM AND UVULA.

It sometimes happens, in cases of congenital fissure of the palate, that the margins of the velum are so far apart as to preclude the possibility of uniting them by any surgical operation, and, at other times, these parts are wholly destroyed by ulceration; it is in such cases, that an artificial velum is required, and to supply which, the ingenuity of art has been taxed to its fullest extent. Various descriptions of mechanism have been invented for this purpose, and it is scarcely necessary to say, that until quite recently, none have been constructed which has performed, to any very considerable extent, the functions of the natural parts. Nor has this desirable object, even yet, been very fully accomplished, but one of the most ingenious contrivances of the kind which has ever been invented, was recently constructed by Mr. Stearns, surgeon, of London. The principle, however, upon which it acts, was not altogether original, as M. Delabarre, had previously constructed a piece of mechanism somewhat similar to it, and composed of the same, though of a less perfect material.

The contrivance employed by Delabarre, consisted of a metallic plate, bent in the form of a horse-shoe, and occupied the place of the posterior part of the naso-palatine floor; the nasal portion was grooved for the reception of the vomer. The palatine surface was concave, and made to resemble the vault of the palate. From each side of this, an arm projected to the first molar, to which it was secured by means of a clasp. To the posterior portion, a piece of caoutchouc, resembling in shape the form of the velum and uvula, was attached. Although this instrument is represented as having performed all the functions of the velum, so far as deglutition and speech are concerned, we are disposed to doubt the correctness of the statement to its full extent, as it has failed to do so in other cases in which it

has been applied, though much advantage, in some instances, has certainly been derived from it.

The instrument constructed by Mr. Stearns, consists of a plate of gold, fitted to the vault of the palate, in the usual manner, and to the upper and posterior margin of which, is attached a flat spiral spring, admitting of easy vibrations backwards and forwards; to the posterior extremity of this is attached a flexible velum, "constructed of Mr. Goodyear's preparation of caoutchouc, which," says Mr. Stearns, has "the property to resist the action of both oils and acids, and at the same time sustaining a high degree of heat." Designating the principal parts of the instrument by the name of body and wings, Mr. S. remarks, "The body of the velum consists of the lamina of caoutchouc, of a somewhat triangular form, and of the same size and shape as the vacant space it is intended to occupy, that being the place which would be indicated by imaginary lines, connecting the opposite sides of the columns, and subtending the vertical angle of the fissure, at which point the velum is connected to the posterior extremity of the spiral spring. The lamina, constituting the body of the velum, is divided into three pieces, which overlap each other. The wings project obliquely forwards and outwards from each lateral margin of the body, and being made to conform to the shape of the columns or sides of the fissure, are seen to rest upon their inner and anterior surfaces, thus covering a portion of the soft parts which constitute the boundaries of the posterior fauces. In like manner, along each lateral margin of the body, there is (in mechanical phrase,) a flange, projecting obliquely, backwards and outwards, and extending along down the posterior surface of the column, it terminates at the inferior angle of the velum. In this way the wing and flange, on the same side, together form a groove fitted to receive the fleshy sides of the fissure. As the preparation of caoutchouc made use of, presents a smooth surface, and yields readily to the slightest pressure, it is found to permit the contact and muscular action of the surrounding soft parts, without

causing any irritation. When, therefore, the sides of the fissure tend to approximate, as in deglutition, gargling the throat, or the utterance of some of the short vowel sounds, the three parts of the body of the velum slide readily by each other, thus diminishing the extent of exposed surface, and thereby imitating, to some extent, muscular contractile action, the force being derived from without, and not, of course, contained within the instrument. During the effort made in speaking, the surrounding muscular parts embrace and close upon the artificial velum, and press it back against the concave surface of the pharynx. The passage to the nares being therefore temporarily closed, the occlusion of sound is accomplished, and articulation made attainable, as the voice or sound, as it issues from the glottis, is thereby directed into the cavity of the fauces, and confined there long enough to receive the impressions made upon it by the tongue, lips, etc., in the formation of the consonant letters."

A velum constructed after the foregoing manner, Mr. Stearns thinks, will be found applicable in all cases, though it will be necessary in the construction of the palate plate, to give it such form and dimensions as may be required by the peculiarities of each case. For example, when the fissure extends through the alveolar border, or when some of the front teeth are wanting, it will be necessary to extend it sufficiently forward to close the opening, or serve as a base for such dental substitutes as may be required.

FIG. 258.

Through the courtesy of Dr. E. G. Tucker, of Boston, we are enabled to add to the foregoing description, an engraving of the instrument, made from a duplicate, which he sent to

us since the publication of the fourth edition of this work, of one, which he and his brother, Dr. J. Tucker, constructed.

In the annexed cut is seen the lower surface of the palate plate and anterior surface of the velum. *a*, the palatine plate; *b*, the flat spiral springs, extending from the posterior margin of the plate to the upper part of the velum; *c c*, wings of the velum; *d d*, the flange; *e*, the central portion. See Fig. 258.

FIG. 259.

FIG. 260.

FIG. 261.

Fig. 259 shows the upper surface of the palate and the posterior surface of the velum and spiral springs. *a*, palate plate; *b*, spiral springs; *c c*, wings of the velum closed; *d d*, the flange as seen above the wings, and *e*, the central portion below the wings, and intended to represent the uvula.

Fig. 260. The velum with the wings separate, showing the central portion, before being attached to the hook, at the lower extremity of the flattened spiral springs. In Fig. 261, is represented a side view of the velum, showing the groove between the flange and the wings, for the reception of the fleshy sides of the fissure.

With a view of restoring the air passages to their normal condition in those cases where the velum has been lost by disease, Dr. S. P. Hullihen invented an instrument consisting of a palate plate with a bi-globular valve attached to it in such a manner as to admit of the egress and ingress of the desired volume of air. We will quote from vol. 1, New

Series of the American Journal of Dental Science, the description which Dr. H. has given of the instrument.

"An artificial palate made upon this plan will be composed of four parts: 1st, A valve, made from gold plate, as thin as it can well be worked; 2d, A spiral spring about an inch long, and of the size usually made for whole sets of teeth; 3d, A slider, one inch and a half in length, and of the width and thickness of a common watch spring; 4th, A plate, larger or smaller, as the case may require, struck up in the usual way, to fit the roof of the mouth.

The size and form of the valve is obtained by taking an impression of the posterior opening of the nares: the plate composing it should be struck up in two parts, front and back, which, when soldered together, makes a hollow body of the form in Fig. 262, letter *a*. At the upper end of the valve, a small pin is soldered, the point of which looks downwards, and of sufficient thickness to fit very tightly in one end of the spiral spring. The spiral spring must be made of such a length as will permit the valve to rest slightly upon the upper surface of the remnants of the lost velum. The slider has a pin in the posterior end, looking upwards to receive the other

FIG. 262.

end of the spiral spring before described. The anterior end of the slider has a small button looking downwards; the slider is attached to the plate by two small clasps, as represented in Fig. 263, *b b*. The plate may be made to cover the entire roof of the mouth, when necessary; or it may be made only sufficiently large to permit the mounting of the slider. These different plates, when put together, particularly if the plate is to cover the whole roof the mouth makes a plate of the form represented by Fig. 262.

FIG. 263.

Fig. 263 shows the attachment of the spiral spring to the valve and slider, *cc*. The staples confine the slider to the plate, *bb*,—and the button on the end of the slider, *d*, by which the valve may be set back

or forward, as desired by the patient, without removing the plate from the mouth.

The plate should be made to fit the several parts for which it is intended, with great exactness. The plate must fit the roof of the mouth, and the teeth to which it may be secured, in a faultless manner. The slider must be arranged so as to permit the valve to be drawn so closely against the posterior opening of the nares, as to close them; or to be pushed back so as to leave them entirely unobstructed. The spiral spring, as I have before remarked, must be made of such a length as will allow the valve to rest slightly upon the upper surface of the remnants of the lost velum. The valve should be sufficiently wide at its base, to overlap the remnants of the velum so far as the parts on each side will permit, without producing irritation—any other part of the valve than the base, should not be allowed to touch, unless when brought forward against the nares. Unless all the parts are so arranged, the palate will not be properly constructed, and will not, of course, answer the desired end.

“Thus it will be perceived, that the peculiarities of this plate, are, first, a valve to fit the posterior opening of the nares. Secondly, the attachment of this valve to a slider, by which the patient is enabled to adjust the valve while in the mouth, in such a way as to admit through the nares, just the quantity of air desired. Thirdly, the mounting of the valve on a spiral spring, which will permit it to vibrate backward and forward, as the breath is inhaled or exhaled; and also to be moved by any muscular action that may re-

main in the remnants of the lost velum, thereby answering, to a great extent, the purposes of a velum."

All the benefit which it is possible to be derived from an appliance of this sort, may, in the majority of cases, we believe, be secured by this instrument. We met with one case, however, in which the muscular action of the remains of the velum against the valve excited so much irritation and retching that it could not be worn. To obviate which, Dr. A. A. Blandy constructed a palate plate of a somewhat different shape, as may be seen from Figs. 264, 265, with a valve composed of two pieces.

To the posterior edge of the palate plate, another plate is soldered. This is about five-eighths of an inch in width where it is united to the palate plate, and half an inch at the posterior extremity, extending upwards and backwards nearly three-fourths of an inch. The two pieces composing the valve are fixed to the lower surface of the plate in such a manner that the contraction of the remains of the velum moves them towards each other. But with their relaxation

FIG. 264.

FIG. 265.

they are immediately separated by two spiral springs attached to the upper surface of the palate plate at one end, and to two delicate springs passing through the plate united to the posterior edge of the first mentioned plate, and at-

tached on the lower surface, one to each part of the valve. The two pieces composing the valve are hollow, each about seven-eighths of an inch in length, and of a conical shape. The bases of the cones are placed posteriorly and the apices anteriorly. The surfaces moving on the plate projecting from the palate plate are flat, and the outer angle of the base of each is rounded. But the several parts of the whole appliance are so distinctly shown in Figs. 264, 265,* that we do not deem a further description of them necessary. In Fig. 264, is seen a lower, and in Fig. 265, an upper view of the apparatus, which has been worn with the greatest comfort and satisfaction since April of the present year, 1852. The patient's speech, although not perfectly restored, is greatly improved, as are also the functions of mastication and deglutition.

ARTIFICIAL PALATES AND OBTURATORS, COMPLICATED WITH ARTIFICIAL TEETH.

When an imperfection of the palate, whether the result of malformation or accident, is accompanied by the loss of one or more teeth, and especially from the anterior part of the mouth, the plate which is employed for remedying the former, should be so constructed as to serve as a base for a substitute for the latter. The idea of complicating a palate plate with artificial teeth, as the author has stated in another place, originated with Fauchard. When a palatine obturator and artificial teeth are to be applied at the same time, they may be connected, and the piece made to answer an excellent purpose, provided there be healthy and natural teeth in the upper jaw to sustain it.

In the construction of an artificial palate or obturator, to which artificial teeth are to be attached, a gold plate of the proper size should be fitted to all that portion of the vault of the palate and alveolar ridge which is to be covered by

* The two pieces composing the valve are purposely separated to show them more distinctly.

it, with a lateral branch on each side extending to the first molar, or the tooth to which it is to be clasped. To these clasps should be soldered, and afterwards artificial teeth fitted and secured in the manner as described in part sixth, of the present treatise. If, however, the upper surface of the plate is to be surmounted with a drum or air chamber, this should be done before the teeth are attached to it. In Fig. 266, may be seen the engraving of a simple palate plate or obturator, with the central and lateral incisors attached to it.

FIG. 266.

When the teeth have all been lost on one side of the mouth, or are too much decayed to serve as a support for an obturator, either with or without artificial teeth, the plate may be constructed with two branches upon the other side, if there be two healthy and firmly articulated teeth, to which clasps can be applied. A piece

FIG. 267.

applied in this manner, in connection with nine artificial teeth, namely, the four incisors, two cuspidati, two bicuspids, and one molar, is shown in Fig. 267. The clasps, as may be perceived by the cut, are intended for a second bicuspid and second molar. Although the molars on the opposite side of the jaw were absent, it was not deemed prudent to increase the weight of the piece, by attaching more than nine artificial teeth to the plate.

FIG. 268.

An artificial palate, complicated with ten artificial teeth, namely, the central and lateral incisors, the cuspidati, the first bicuspid of the left side, the first and second of the right, as well as the first molar, is represented in Fig. 268. The clasps, as may be seen, are for the first molar of the left side, and the second of

the right. The opening in the palate to be covered by the plate in this case, extended from the alveolar border backwards a little more than an inch, and was about seven-eighths of an inch in width.

The functions of mastication, deglutition and speech, which were all very greatly impaired by the opening in the palate and loss of so many of the teeth, were all, in a great degree, restored by the piece here represented.

The author would here refer to an obturator, complicated with artificial teeth, constructed by Mr. Warren Rowell, of New York, and the great difficulty to be overcome in this case, according to report made of it by Dr. Griscom,* was the want of teeth in the upper jaw to sustain it, and the great size of the opening in the palate, the vomer and turbinated bones having been destroyed. Upon examination, however, Mr. Rowell found that the posterior portion of the palatine aperture was formed, "to a considerable extent, of a semi-cartilaginous substance, possessing sufficient elasticity to allow a larger body than the opening to be pushed up through it, and that when so forced up, it would be supported above the aperture by the edge retiring to its original position." This, he hoped, would support a light plate,

* Vide New York Journal of Medicine, vol. viii, No. 23, p. 187.

if the obturator could be so shaped as to rest upon the cartilaginous ledge, after it was introduced.

Without quoting the description which is given of his method of procedure, it will be sufficient to state, that the obturator, which he constructed, consisted of a plate larger than the opening in the palate, and covering the anterior part of the alveolar ridge, to which artificial teeth were attached, and an irregularly shaped drum or air chamber, larger above than below, where it was connected with the palate plate. The neck of this bulb or drum, is of the exact size of the opening in the palate, and the upper part or summit has several depressions, which correspond with the irregular "surfaces of the remaining nasal bones."

FIG. 269.

FIG. 270.

The anterior part of the palate plate, to which the teeth are attached, as may be seen in Fig. 269, is composed of two plates, "to compensate by its thickness for the deficiency of the alveolar ridge." The drum is seen rising from the palate plate, to which it is soldered.

In Fig. 270 is represented a lateral view of the piece. The palate plate and drum are composed of fine gold, and made very light.

At the time Mr. Rowell constructed this obturator, we are assured, by Dr. Griscom, he had never heard of nor seen "Delabarre's proposed operation," so that it would seem that the obturator which he constructed was original with himself. We are also informed that it has been worn since

1841, and as yet, (1847,) has not caused any appreciable increase in the size of the opening. That this, however, will ultimately be the case, we think there can be no question.

Dr. Mütter gives an engraving of an artificial palate, complicated with several artificial teeth and a metallic velum connected with the palate by means of a hinge, constructed by Mr. Neil, a dentist, of Philadelphia, which is represented as having answered an excellent purpose.* It is difficult to conceive, however, how a gold plate of an oval shape, could be made to perform the functions of the velum palati. So far as an imperfection in the hard palate is concerned, the evil, we know, may be remedied by covering the opening with a metallic plate, but the loss of the soft palate cannot be replaced with any hard unyielding material, so as to restore the functions of the natural parts.

The most complicated, and at the same time, ingenious piece of mechanism, of which we have ever heard, for replacing the loss of the entire palate, including the velum and nearly all the teeth of the upper jaw, was invented by M. Delabarre, but in consequence of its weight, from the amount of material in it, as well as the complexity of the instrument, it failed to realize the sanguine expectations of the inventor, although he states that it fully answered the purpose for which it was designed. Subsequent experiments, however, have been less successful, and as this method of constructing artificial palates has long since been abandoned, we do not think it necessary to quote the description which he has given of it.

Instead, therefore, of employing this complicated instrument, a simple palate plate, raised upon its upper surface, with a velum like the one constructed by Mr. Stearns, or

* Vide Liston's and Mütter's Surgery,

with Hullihen's or Blandy's valve, with artificial teeth attached to it, will be found to answer a much better purpose, in a case like the one for which M. Delabarre's complicated piece of mechanism was fabricated. As it is not probable that such an appliance will ever be constructed again, we do not deem it necessary even to copy the engraving furnished by the author.

M. Desirabode proposes a kind of platina obturator for congenital fissure of the palate, by which he thinks the sides of the alveolar border may be so approximated as to favor the union of the divided parts. It consists of a platina plate fitted to the vault of the palate and fastened to the teeth by means of three crotchets, (clasps,) soldered to each side, so as to cap the canine teeth, the bicuspid, and two of the molar teeth, bent upon the alveolar border, in such a manner as to maintain the whole pressure. After the plate, with these appendages, has been well adapted, it is divided from before backwards along the median line, and then a piece is removed from each side, so that the two edges may be separated about half an inch from each other. The two half plates are now united by means of a thick and resisting band of caoutchouc, made fast by riveting. The plates thus united, form a smaller obturator than the plate before it was divided, so that it can only be applied by putting the caoutchouc upon the stretch, which is effected by means of two stocks, so contrived as to force the two plates asunder. After the plate is properly adjusted, these are removed, when, by the contraction of the caoutchouc, the sides of the alveolar border are gradually made to approach each other.

It sometimes happens that an imperfection of the palate is accompanied by an opening into the maxillary sinus. In this case, the palatine plate should be large enough to close both openings, and the loss of the alveolar border replaced by means of a raised plate, soldered to the lower surface of the palate plate, and to which artificial teeth may be attached.

In conclusion, it only remains to observe that the same attention is required to prevent injury to the natural teeth, which serve as a support to an artificial palate or obturator as to those which are used for the retention of dental substitutes, and as full directions have already been given upon this subject, it is not necessary to repeat them here.
